3. Daily weighing is necessary to detect a rapid weight gain that indicates fluid retention (2 pounds in 24 hours) and to measure weight loss resulting from the diuretic.

4. These instructions ensure accuracy of the weight so that comparison to the baseline weight detects a weight gain or loss.

5. Weight increase reporting guidelines are as follows: increase of 2 to 3 pounds in 1 to 2 days.

Mrs. Eden

1. No, Mrs. Eden is not tolerating this activity, as evidenced by her increased respiratory rate and apical rate.

2. Steroids, immunosuppressive therapy, depression, and fatigue could be causing her poor appetite.

REVIEW QUESTIONS

1. The nurse is providing patient education. The patient asks the nurse what HF is. Which of the following is the nurse’s best response?

   1. “The heart pumps too much blood into the pulmonary veins.”
   2. “The heart is unable to pump enough blood for the body’s oxygen needs.”
   3. “HF is a buildup of blood in the aorta from the heart’s left ventricle.”
   4. “With a failing heart, the heart stops beating, so blood is not pumped out.”

2. The nurse is to give bumetanide (Bumex) to a patient and reviews laboratory results. Which of these results requires action by the nurse?

   1. potassium 3.0 meq/dL
   2. sodium 135 meq/dL
   3. International normalized ratio 0.8
   4. Partial thromboplastin time 36 seconds

3. A patient who has been treated for HF is being discharged from the hospital on 20 mg furosemide (Lasix) daily. Which of the following statements by the patient would indicate understanding to the nurse for instructions on taking this medication?

   1. “I will take the Lasix in the morning.”
   2. “I will take the Lasix at bedtime.”
   3. “I will drink lots of fluids with the Lasix.”
   4. “I will take it with meals.”

4. The nurse is caring for a patient receiving bumetanide (Bumex) to reduce preload for HF. While collecting data, the nurse sees the patient has less ankle edema and jugular venous distention than earlier. The next dose of bumetanide is scheduled in 1 hour. Which of the following actions should the nurse take?

   1. Notify the physician.
   2. Hold the bumetanide.
   3. Give the bumetanide as scheduled.
   4. Give the bumetanide early.

5. The nurse is reinforcing teaching for a patient with chronic HF. Which of the following assessments should the nurse teach the patient to perform to monitor fluid status at home?

   1. Weigh daily.
   2. Weigh weekly.
   3. Weigh biweekly.

6. A 160-pound patient is to receive cyclosporine (Neoral) 12.5 mg/kg daily in two divided doses. How many milligrams will the patient receive with each dose? Fill in the blank.

   Answer: ________________ mg

Answers can be found in Appendix C.

Understanding the Hematologic and Lymphatic Systems
KEY TERMS

- ecchymoses (EK-ih-MOH-siss)
- hemolysis (hee-MAHL-eh-sis)
- lymphedema (LIMPF-uh-DEE-mah)
- petechiae (puh-TEE-kee-eye)
- purpura (PURR-purr-uh)

LEARNING OUTCOMES

1. List the components of blood.
2. List the components of the lymphatic system.
3. Describe how changes in the blood or lymph systems can manifest as disease processes.
4. Describe the sequence of events in the process of blood clotting.
5. Identify data to collect when caring for a patient with a disorder of the hematologic or lymphatic system.
6. Identify laboratory and diagnostic studies that are used when evaluating the hematologic and lymphatic systems.
7. Plan nursing care for patients undergoing diagnostic tests of the hematologic or lymphatic systems.
8. List common therapeutic measures used for patients with hematologic and lymphatic disorders.
9. Discuss the role of the licensed practical nurse/licensed vocational nurse (LPN/LVN) in administering blood products.
The hematologic system includes the bone marrow, blood, and blood components. The lymphatic system includes lymph nodes and nodules, which filter pathogens for destruction, and lymph vessels, which return lymph to the blood.

**Blood**

The general functions of blood are transportation of substances; regulation of body temperature, pH, and fluid balance; and transport of cells that offer the body protection.

The human body contains 4 to 6 L of blood; approximately 45% is formed elements, and the remainder is plasma (Figure 27.1). All formed elements are produced from stem cells in the red bone marrow (hematopoietic tissue), found in flat bones, irregular bones, and the epiphyses of long bones (Figure 27.2). T-lymphocyte maturation and differentiation occurs in the thymus. Table 27.1 shows normal blood cell counts.

**Plasma**

Plasma, the transporting medium, is about 91% water. Plasma proteins are synthesized by the liver and include clotting factors, albumin, and globulins. Clotting factors such as prothrombin and fibrinogen circulate until activated for coagulation. Albumin helps maintain blood volume and pressure by pulling tissue fluid into the venous ends of the capillary networks. Alpha and beta globulins are carrier molecules for substances such as fats, and gamma globulins are antibodies produced by lymphocytes.

Plasma is also important in maintaining body temperature. The water of plasma is warmed by passage through active lymphocytes.

**Red Blood Cells**

Mature red blood cells (RBCs) are biconcave disks without nuclei; they carry oxygen bonded to the iron in hemoglobin (Hgb). Oxyhemoglobin is formed in the pulmonary capillaries when oxygen bonds to the iron of hemoglobin (Hgb). Once hemoglobin gives up its oxygen to the cells of the body, it becomes reduced hemoglobin. The amount of hemoglobin in RBCs, the amount of iron in that hemoglobin, and the number of RBCs determine the amount of oxygen the blood can carry. Reduced oxygen-carrying capacity causes anemia, which results in symptoms such as shortness of breath and fatigue.

Hypoxia stimulates the kidneys to secrete erythropoietin, which increases the rate of RBC production and thus the oxygen-carrying capacity of the blood. A reticulocyte (immature RBC) becomes a mature RBC when it ejects its nucleus. This causes the characteristic biconcave disk shape. The presence of large numbers of reticulocytes in peripheral blood indicates an insufficient number of mature RBCs to meet the oxygen demands of the body.

Sufficient dietary intake of protein and iron to synthesize hemoglobin is required for normal production of RBCs. The vitamins folic acid and vitamin B₁₂ are needed for DNA synthesis in the stem cells of the red bone marrow; mitosis is dependent on the ability to produce new sets of chromosomes. Vitamin B₁₂ is called extrinsic factor because it comes from an

All blood cells can trace their beginnings to a specific type of bone marrow cell called a stem cell (also called a pluripotent stem cell). Stem cells are unspecialized cells that give rise to immature red blood cells, white blood cells, and platelet-producing cells.

The “offspring” of the stem cell divide further, ultimately becoming a mature red blood cell, white blood cell, or platelet.

extrinsic source: food. The parietal cells of the stomach lining produce intrinsic factor, which is a chemical that combines with vitamin B₁₂ to promote its absorption in the small intestine.

RBCs live for about 120 days and then become fragile and are phagocytized by fixed macrophages in the liver, spleen, and red bone marrow (Fig. 27.3). Diseases such as malaria and sickle cell anemia cause an accelerated destruction of RBCs (hemolysis). The resulting release of excess hemoglobin can cause the blood level of bilirubin to rise. Elevated bilirubin levels discolor the sclerae, skin, and mucous membranes to a yellowish orange hue; this condition is known as jaundice.

Each person has an inherited blood type, which is determined by the antigens present on the RBCs. The two most important type categories are the ABO group and the Rh factor. The ABO type (A, B, O, or AB) indicates the antigens present (or not present, as in type O) on the RBCs. The plasma contains antibodies for antigens that are not present in the blood. These antibodies can interact with antigens in transfused blood if the donor’s blood does not match the recipient’s blood (Table 27.2). To be Rh-positive means that the D antigen is present on the RBCs; Rh-negative means that the antigen is not present. Rh-negative people do not have natural antibodies to the D antigen but will produce them if given Rh-positive blood.

**White Blood Cells**

WBCs are larger than RBCs and have nuclei when mature. The granular WBCs (neutrophils, eosinophils, and basophils) and the agranular WBCs (lymphocytes and monocytes) are produced in the red bone marrow; the T lymphocytes complete their development in the thymus. The T lymphocytes and B lymphocytes become activated, proliferate, and differentiate in the lymph nodes, spleen, and lymphatic nodules. Table 27.1 shows normal values and percentages for each type of WBC in a differential count. WBCs function within tissue fluid, as well as the blood; all are involved in the immune or inflammatory response to injury.

Monocytes become macrophages in tissues, which phagocytize pathogens and viral-infected cells; neutrophils are more numerous and phagocytize foreign materials. Eosinophils combat the effects of histamine, detoxify foreign proteins during allergic reactions, and respond to parasitic infections. Basophils release heparin and histamine as part of inflammatory reactions. There are two groups of lymphocytes: T cells and B cells. T cells may be helper, suppressor, killer, or memory T cells. B cells become memory cells and plasma cells; plasma cells produce antibodies to foreign antigens.

**Platelets**

Platelets are formed in the red bone marrow; they are fragments of large cells called megakaryocytes. Platelets are involved in all mechanisms of hemostasis: vascular spasm, platelet plugs, and chemical clotting.

After a platelet plug is formed, one of two pathways initiates a cascade of events to bring about coagulation. When a blood vessel or surrounding tissues outside the blood are damaged, the extrinsic pathway begins. Conversely, when platelets adhere to damaged endothelium and release clotting factors, this initiates the intrinsic pathway. Either way, the end result is a fibrin clot (Figure 27.4).

Excessive clotting in the vascular system is prevented in several ways. The smooth endothelial lining of blood vessels repels platelets so that they do not stick to intact vessel walls. Heparin produced by mast cells inhibits the clotting mechanism, and

*Emphasized text*
Iron is transported to the bone marrow where it’s used to create new hemoglobin. In the process, hemoglobin is broken down into its two components of globin and heme. Heme is broken down into iron and bilirubin. Bilirubin is excreted into the intestines as part of bile.

Globin is further broken down into amino acids. The amino acids are used for energy or to create new proteins.

Heme
Fe³⁺
Bilirubin
Iron

Macrophages in the liver and spleen ingest and destroy old RBCs.

Lymphatic Vessels

Lymph is tissue fluid that has entered lymph capillaries. Lymph must be returned to the blood to maintain blood volume and blood pressure. Lymph capillaries are found in most tissue spaces; they anastomose, forming larger and larger lymph vessels, which have valves to prevent backflow. Lymph from areas below the diaphragm and the upper left half of the body enters the thoracic duct and is returned to the blood in the left subclavian vein. Lymph from the upper right body enters the right lymphatic duct and is returned to the blood in the right subclavian vein.

Lymph Nodes and Nodules

Lymph nodes are masses of lymphatic tissue along the pathways of the lymph vessels. They house activated lymphocytes and macrophages. Nodes are scattered throughout the body and are concentrated in the cervical, axillary, and inguinal regions, where they are well situated to remove pathogens before the lymph is returned to the blood. Foreign materials are phagocytized by fixed macrophages; lymphocytes form immune responses.

Lymph nodules (or mucosa-associated lymphatic tissue) are small masses of lymphatic tissue found just beneath the

Both the extrinsic and intrinsic pathways result in the formation of factor X. (This occurs in a single reaction in the extrinsic pathway, while, in the intrinsic pathway, four different reactions are required to activate factor X.) Either way, once factor X is activated, the formation of a blood clot follows a common pathway, as shown here.

The end result of both the extrinsic and intrinsic pathways is the production of an enzyme called prothrombin activator. Prothrombin activator acts on a globulin called prothrombin (factor II)...

...converting it to the enzyme thrombin. Thrombin transforms the soluble plasma protein fibrinogen into fine threads of insoluble fibrin.

The sticky fibrin threads form a web at the site of the injury. Red blood cells and platelets flowing through the web become ensnared, creating a clot of fibrin, blood cells, and platelets. A blood clot can effectively seal breaks in a smaller vessel; however, blood clotting alone may not stop a hemorrhage from a large blood vessel.

epithelium of all mucous membranes. Mucosal-lined tracts (respiratory, digestive, urinary, and reproductive) have openings to the external environment. Any natural body opening is a potential portal of entry for pathogens; microbes that penetrate the epithelium are usually destroyed by the macrophages in the lymph nodules. The tonsils, which protect the oral and nasal portions of the pharynx, are familiar examples of lymph nodules.

**Spleen**

The spleen is located in the upper left quadrant of the abdominal cavity, just below the diaphragm, behind the stomach. The lower rib cage protects the spleen from mechanical injury. In the fetus, the spleen produces RBCs, a function assumed by the bone marrow after birth.

The spleen has several functions after birth. It contains B cells and T cells, which conduct immune responses. It also contains fixed macrophages that phagocytize pathogens and worn or defective blood cells and platelets. The heme unit from RBC destruction forms bilirubin. Bilirubin is sent to the liver by way of portal circulation for excretion in the bile. The spleen stores up to one-third of the body’s platelets.

The spleen is not considered a vital organ because other organs compensate for its functions if the spleen must be removed. The liver and red bone marrow also remove worn RBCs from circulation, and the many lymph nodes and nodules produce lymphocytes and macrophages for protection. However, a person without a spleen is somewhat more susceptible to certain bacterial infections, such as pneumonia and meningitis.

**Thymus**

The thymus is located in the mediastinum, anterior to the trachea. With increasing age, the thymus atrophies; relatively little thymic tissue is found in adults. The thymus contains T lymphocytes, or T cells, that mature and proliferate. Thymic hormones contribute to the maturation of the T cells. (Immunity is covered in Unit 4.)
Aging and the Hematologic and Lymphatic Systems

Older adults undergo a number of changes in the hematologic and lymphatic systems (Fig. 27.6).

NURSING ASSESSMENT OF HEMATOLOGIC AND LYMPHATIC SYSTEMS

Health History

A thorough nursing assessment starts with an in-depth patient history (Table 27.3). Specific problems that might be seen in

</tr>
</tbody>
</table>
Patients with hematologic disorders include abnormal bleeding, petechiae (small purplish hemorrhagic spots under the skin), ecchymoses (larger areas of discoloration from hemorrhage under the skin), and purpura (hemorrhage into the skin, mucous membranes, and organs), as well as fatigue, weakness, shortness of breath, and fever. Fatigue, malaise, and weight loss can accompany cancers of the lymphatic system.

Begin by obtaining the patient’s biographical data, marital status, occupation, religion, age, sex, and ethnic background. This information can give you valuable clues to risk factors. For example, even though hemophilia almost always occurs in males, females can carry the gene. Sickle cell anemia occurs mostly in African Americans but also affects people of Mediterranean or Asian ancestry. Pernicious anemia occurs most often in people of northern European ancestry. By carefully collecting this information, you can obtain important clues that will help pinpoint a patient’s problem. Finally, focus on collecting data about symptoms by using the WHAT’S UP? format presented in Chapter 1.

A complete review of past illnesses and family history is always indicated and can provide some valuable information. A social history is also useful. After developing good rapport with the patient, explore dietary and alcohol intake habits, any drug use or abuse, and sexual habits, all of which can cause changes in the hematologic system.

An occupational review can reveal exposure to some hazardous substances that can cause bone marrow dysfunction. Certain occupations, such as working in a paint factory, tool and dye processing, and even dry cleaning can be related to the formation of some hematologic cancers. Military history can also reveal sources of exposure that can help during the diagnostic phase for hematologic and lymphatic disorders.

**Physical Examination**

Hematologic and lymphatic disorders can involve almost every body system, so each system must be assessed. Signs and symptoms of hematologic and lymphatic disorders can be vague, such as shortness of breath or fatigue. A careful assessment will guide nursing care but may also uncover important data that should be reported to the primary care provider. Table 27.4 reviews objective data that should be collected and possible interpretations of findings.

**Coagulation Tests**

Coagulation tests are shown in Table 27.5. Agglutination tests include ABO blood typing, Rh typing, crossmatching of blood samples, and direct antiglobulin tests (also known as Coombs’ test).

**Bone Marrow Biopsy**

Biopsy information can be obtained through removal of a small amount of bone marrow with a needle. Aspiration of marrow is done to obtain a specimen that can be viewed under the microscope. Purposes of this test include the diagnosis of hematologic disorders; monitoring the course of treatment; discovery of other disorders, such as primary and metastatic tumors, infectious diseases, and certain granulomas; and isolation of bacteria and other pathogens by culture.

An accurate bone marrow specimen in an adult can be obtained from the sternum, the spinous processes of the

---

**Mrs. Brown**

Mrs. Brown is on warfarin (Coumadin) therapy because of a blood clot in her leg. She has a prothrombin time (PT) drawn at the lab, and the result is 12 seconds. Will the health care provider (HCP) most likely increase Mrs. Brown’s daily dose of warfarin, decrease it, or leave it the same? (Use Table 27.5 to figure out the answer.)

Suggested answers are at the end of the chapter.
When a patient has a bacterial infection, the neutrophils, which are the most numerous of the WBCs, rise in number to help fight it. There are two forms of neutrophils: segmented (mature) and bands (immature). Initially, the number of segmented neutrophils rises. Then, as the infection becomes more severe, the number of immature bands begins to rise.

An easy way to remember this is that the WBCs are part of the body’s defenses, just like the military is part of a country’s defenses. When needed, sergeants who are fully trained or mature are called to assess the battle first. If they are unable to fight off the invading enemy, new recruits being trained in boot camp are called in to help.

So segmented neutrophils (called Segs) are like the Sergeants, fully mature and ready to fight. The Bands are like Boot camp recruits, immature and not fully trained. However, in an acute infection, bands are needed to keep the body from being overwhelmed by the infection and losing the battle.

As you look at the differential WBC count, if the segs are elevated but the bands are normal, the infection is probably new. If the bands are also elevated, the infection is worsening. The more elevated they are, the more severe the infection.

Lymphocytes fight viral infections and are elevated during a virus. A common pattern in the WBCs is produced for either a bacterial or viral infection. If the infection is acute bacterial:

- Segs ↑
- Bands ↑
- Lymphocytes ↓

If the infection is viral:

- Segs ↓
- Bands ↓
- Lymphocytes ↑

This can be remembered as the bone marrow producing the cells most needed during the time of viral infection and reducing production of those cells least needed. When the infection is resolved, all of the cells should return to their normal production levels.

</tr>
</tbody>
</table>

vertebrae, or the anterior or posterior iliac crest. Bone marrow biopsy is considered a minor surgical procedure and is carried out under aseptic conditions. For iliac crest aspiration, the patient is placed comfortably on the side with the back slightly flexed. The posterior iliac crest is cleansed and covered with antiseptic solution. The skin, subcutaneous tissue, and periosteum are anesthetized using 1% or
2% lidocaine (Xylocaine). A 2- to 3-mm incision is made to facilitate penetration with a 14-gauge, 2- to 4-cm-long bone marrow needle. The incision is made to a void introducing a skin plug into the marrow cavity, which can cause infection.

The nurse’s role in bone marrow biopsy is multifaceted. You may need to help coordinate between the laboratory and the HCP, establishing a time to do the procedure and determining who obtains the supplies, such as the disposable bone marrow aspiration tray and specialized needles, from the central supply department. Be sure to obtain an order for an analgesic and administer it before the procedure. Assist with positioning the patient before and during the procedure, help the patient maintain the needed position, and observe the aspiration site for bleeding and infection. You can also provide emotional support to the patient before, during, and after the procedure.

**BE SAFE!**

For all surgical and nonsurgical invasive procedures, the intended procedure site should be marked. Before the start of any invasive procedure, a final verification process is conducted to confirm the correct procedure, for the correct patient, at the correct site. The patient is involved in the verification process when possible (Joint Commission’s 2014 National Patient Safety Goals, © The Joint Commission, 2013. Reprinted with permission).

**Lymphangiography**

Problems in the lymph system, such as lymphoma or metastatic cancers, can be evaluated using lymphangiography. This procedure involves injection of a dye into the lymphatic vessels of the hand or foot. X-ray views are then taken to determine lymph flow or blockages. X-ray examinations are repeated in 24 hours to assess lymph node involvement.

Following the procedure, the HCP may order a pressure dressing and immobilization of the injected limb to prevent bleeding at the site. Continue to monitor the limb for swelling, circulatory status, and changes in sensation. Warn the patient that the skin, urine, or feces may be tinged blue from the dye for about 2 days.

**Lymph Node Biopsy**

If a lymph node is enlarged, it may be biopsied to determine whether the cause is infection or malignancy. A biopsy is done with a needle aspiration or surgical incision. A small dressing or bandage is applied to the site. Following the procedure, review signs of bleeding and infection with the patient that should be reported to the HCP.

**THERAPEUTIC MEASURES FOR THE HEMATOLOGIC AND LYMPHATIC SYSTEMS**

**Blood Administration**

Blood may be administered by a registered nurse (RN) or licensed practical nurse/licensed vocational nurse (LPN/LVN), depending on the state in which you practice. Some states require that only RNs administer blood. As an LPN/LVN, you may be called on to assist with proper identification procedures and monitoring of vital signs during the transfusion.

Table 27.6 lists blood components that may be ordered. The main goals are to administer them safely and to avoid mistakes. Make sure to use proper identifying information to ensure that the right patient is receiving the right blood products (Fig. 27.7). In addition, it is important to note that some institutions require a special transfusion consent form to be completed and present in the patient’s chart. A careful system most often used in health care institutions is found on DavisPlus.

**FIGURE 27.7** Two nurses check a patient’s identification before administering a unit of blood.
BE SAFE!

BE VIGILANT! Eliminate transfusion errors related to patient misidentification. Before initiating a blood or blood component transfusion:

- Match the blood or blood component to the order.
- Match the patient to the blood or blood component.
- Use a two-person verification process or a one-person verification process accompanied by automated identification technology, such as bar coding.
- When using a two-person verification process, one individual conducting the identification verification is the qualified transfusionist who will administer the blood or blood component to the patient.
- When using a two-person verification process, the second individual conducting the identification verification is qualified to participate in the process, as determined by the hospital.

Special Precautions

FLUID COMPATIBILITY. Make sure to use only normal saline solution to help dilute the blood and to flush the intravenous (IV) lines before and after the transfusions. Solutions that contain dextrose can cause red cells to lyse (i.e., their cell membranes are destroyed), and solutions with calcium can cause the blood product to clump, clot, or not infuse at all.

TIMING. Transfuse each unit of packed cells over 2 hours. If it must transfuse more slowly because of the patient’s condition, make sure the unit does not hang longer than 4 hours to prevent deterioration and bacterial proliferation.

FILTERING. Filters are used with blood administration tubing to prevent potentially harmful particles from entering the patient. Most often, the filter that comes with the transfusion tubing is sufficient for each unit of packed RBCs. In some situations, special filters may be needed to remove leukocytes or microaggregates. The blood bank can advise in these situations.

WASHED OR LEUKOCYTE-DEPLETED BLOOD. In some instances packed RBCs (PRBCs) are ordered as “washed” and often arrive from the blood bank in a special round bag. The washing process removes almost all of the plasma and can decrease the risk or severity of a febrile reaction. In addition, leukocyte filters may be used to completely remove all WBCs. This removal process is used in cases in which many transfusions are anticipated, because it decreases the chance of antigen sensitization. It can also reduce transmission of certain viruses, such as cytomegalovirus.

WARMED BLOOD. If the patient has had a severe bleeding episode and the nurses are helping to give replacement therapy through rapid, multiple transfusions, the HCP may consider ordering a blood warmer. It works just as the name implies, warming the cold blood from the blood bank to the standard body temperature of 98.6°F (37.0°C). This warming helps prevent hypothermia, which can cause heart dysrhythmias, and shivering, which can destroy blood cells and platelets.

Monitoring

Whether or not you actually administer the blood, you will likely participate in monitoring to prevent complications or to detect and treat them quickly if they occur. Stay with the patient for the first 15 minutes of the blood transfusion to assess for any immediate reactions. The 15 minutes begins when the blood enters the vein. If saline solution is in the tubing, it may take several minutes before the blood reaches the patient. Check and document vital signs before starting the transfusion, after the blood has been infused, and after the infusion is complete. Some institutions require vital sign monitoring every 15 to 30 minutes during the earliest part of the transfusion and then slightly less often for the duration of the infusion. Always follow institution guidelines. During the transfusion, assess the patient for signs and symptoms of complications.

Complications

Quick detection of complications can be lifesaving. It is easy to think of transfusing blood components as a routine procedure because it is a common activity. Do not be fooled. It is a serious procedure that can be life threatening if errors occur. Complications include febrile reactions, hypersensitivities, hemolytic reactions, anaphylaxis, circulatory overload, and even death. Regular monitoring according to institution policy can help detect complications early when treatment can be most effective.

FEBRILE REACTION. By far the most common reaction is fever (febrile reaction). It occurs up to 2% of the time. Make sure that blood never transfuses for more than 4 hours. The risk of a febrile reaction goes up with each unit of blood product given to the patient. Many times, febrile reactions occur after the transfusion is completed, but they can occur at any time. This is the reason for obtaining a set of baseline vital signs, including the patient’s temperature. Once a febrile reaction begins, the most common signs are an increasing fever and chills, which can be severe. Other symptoms can include headache and back pain. If febrile symptoms occur, stop the transfusion and notify the HCP. Acetaminophen may be ordered. If a hemolytic reaction is not suspected, the HCP may order the transfusion to continue once the patient is more comfortable. Administering leukocyte-depleted blood can usually prevent future febrile reactions.

URTICARIAL REACTION. Urticarial (hive) reactions are considered to be minor allergic reactions and are usually associated with antigens in the plasma accompanying the transfusion.
There may be a fever, but the cardinal sign is the appearance of urticaria, a hive-like rash. On discovery of this reaction, stop the transfusion and notify the HCP immediately. Expect that the patient will be given a dose of an antihistamine, such as diphenhydramine (Benadryl). If the transfusion is restarted, continue to monitor the patient closely. Again, make sure the 4-hour administration rule is not violated.

**HEMOLYTIC REACTION.** The most deadly and, fortunately, the rarest of the possible reactions is an acute hemolytic reaction. The cause of this reaction is transfusion of incompatible blood. The result is hemolysis (destruction) of RBCs. This type of serious reaction is usually noticed within minutes of starting the transfusion. The patient may report back pain, chest pain, chills, fever, shortness of breath, nausea, vomiting, or a feeling of impending doom. As the reaction progresses, the patient begins to show signs of shock, hypotension, oliguria, and decreased consciousness. Late signs and symptoms include those associated with disseminated intravascular coagulation: uncontrollable bleeding from many different sites at the same time, usually ending in death.

At the first sign of this type of reaction, immediately stop the transfusion and stay with the patient. Institute emergency procedures to notify the charge nurse, the HCP, and the blood bank. Keep the vein open with normal saline using a new tubing set (ensuring that no more incompatible blood is administered) so that emergency drugs can be administered. High volumes of fluids are administered to decrease shock and hypotension, and high doses of diuretics are given to promote urine flow because the kidneys are the most likely organs to be damaged. Dialysis may be necessary.

**ANAPHYLACTIC REACTION.** Anaphylactic reactions are not common but may be seen more often in patients who have received many transfusions or have had many pregnancies. Usually, the source of the anaphylaxis is sensitization to immune globulins passed from the donor blood product. In this type of reaction, the very first milliliters of blood containing the allergens to pass into the patient’s system may be enough to cause the patient to develop respiratory or cardiovascular collapse. Other more common symptoms include severe gastrointestinal cramping, instant vomiting, and uncontrollable diarrhea.

If the patient exhibits these signs and symptoms, stop the transfusion at once and stay with the patient. Have someone else notify the RN and the HCP using institutional emergency procedures. Emergency resuscitation measures, including cardiopulmonary resuscitation if necessary, must be instituted until the Rapid Response or code team arrives. Expect the patient to be intubated and receive oxygen, steroids, and other drugs as needed for life support. After the emergency has passed, this patient will likely need to receive transfusions from frozen, deglycerolized blood cells.

**CIRCULATORY OVERLOAD.** Circulatory overload is caused by rapid transfusion in a short period, particularly in older and debilitated patients. Usual signs and symptoms include chest pain, cough, frothy sputum, distended neck veins, crackles and wheezes in the lung fields, and increased heart rate. If symptoms occur, stop the transfusion and notify the HCP.

Anticipate administration of diuretics, which help get rid of the excess fluid. The transfusion may be restarted later at a slower rate (see “Gerontological Issues”).

**Gerontological Issues**

Older patients have less cardiac and renal ability to adapt to changes in blood volume, so they have a much higher risk of fluid overload when receiving IV infusions or blood transfusions. Carefully monitor lung sounds and vital signs both before and during a blood transfusion. New onset of dyspnea, crackles, hypertension, or bounding pulse during any infusion should be reported to the registered nurse or HCP immediately.

---

**SUGGESTED ANSWERS TO**

**CRITICAL THINKING**

- **Mrs. Brown**

  The HCP will most likely increase Mrs. Brown’s warfarin dose. Note in Table 27.5 that the PT for a patient on warfarin should be 1.5 to 2.0 times normal. That is the reason the warfarin is ordered—to prolong the time it takes for blood to clot. If a normal PT is 9.5 to 11.3 seconds, a therapeutic PT for Mrs. Brown would be 14.25 seconds (9.5 × 1.5) to 22.6 (11.3 × 2.0). Her result of 12 seconds is not therapeutic.
Chapter 27  Hematologic and Lymphatic System Function, Assessment, and Therapeutic Measures

REVIEW QUESTIONS

1. Which of the following actions should the nurse prioritize when taking care of a patient with a platelet count of 23,000/mm³?
   1. Request an order for an anticoagulant.
   2. Protect the patient from injury.
   3. Encourage the patient to drink plenty of fluids.
   4. No action is necessary. This is a normal level.

2. A nurse is assessing a patient and finds small red-purple dots over most of his skin surfaces. The patient denies noticing them before. Which action should the nurse take first?
   1. Report the findings immediately to the RN or HCP.
   2. Document the findings objectively in the medical record.
   3. Assist the patient to apply lotion.
   4. Administer an antihistamine as needed.

3. A nurse is preparing a patient for lymphangiography. Which statement by the patient shows that more teaching is needed?
   1. “My skin might turn a bluish color.”
   2. “I will need a sandbag on my groin to prevent bleeding.”
   3. “My nurse will be checking my circulation routinely after the procedure.”
   4. “I will need more X-rays tomorrow.”

4. Which of the following activities should be carried out to keep the patient safe before starting a blood transfusion? Select all that apply.
   1. Match the blood to the order.
   2. Match the patient to the blood.
   3. Match the room number to the order.
   4. Check the patient’s vital signs.
   5. Check the temperature of the blood.
   6. Check the patient’s weight.

5. A nurse is monitoring a patient during a blood transfusion. After the blood has been hanging for 30 minutes, the patient’s temperature rises from 98.6°F (37.0°C) at baseline to 101.0°F (38.3°C). The patient also experiences severe chills. Which action should the nurse take first?
   1. Document the vital signs in the medical record.
   2. Administer acetaminophen for the fever.
   3. Notify the HCP of the change.
   4. Stop the transfusion and hang normal saline solution.

Answers can be found in Appendix C.

LEARNING OUTCOMES

1. Explain the pathophysiology of each of the hematologic and lymphatic disorders discussed in this chapter.
2. Describe the etiologies, signs, and symptoms of each disorder.
3. Identify tests used to diagnose each of the disorders.
4. Describe current therapeutic measures for each disorder.
5. List data you should collect when caring for patients with disorders of the hematologic or lymphatic systems.
7. Plan nursing care for patients with lymphatic disorders.
8. Explain how you will know if your nursing interventions have been effective.
9. Describe precautions you should institute to prevent bleeding in patients with clotting disorders.
10. Identify nursing care and teaching you will provide for patients undergoing a splenectomy.
HEMATOLOGIC DISORDERS

Patients with hematologic disorders have problems related to their blood. What do you suppose happens when there are too many blood cells, or too few, or the cells are defective?

- When red blood cells (RBCs) are affected, oxygen transport is also affected, causing symptoms related to poor oxygenation.
- When white blood cells (WBCs) are affected, the patient is unable to effectively fight infections.
- If platelets or clotting factors are affected, bleeding disorders occur.

DISORDERS OF RED BLOOD CELLS

Anemias

The term anemia describes a condition in which there is a deficiency of RBCs, hemoglobin, or both, in the circulating blood. Because hemoglobin carries oxygen, this results in a reduced capacity to deliver oxygen to the tissues, producing symptoms such as weakness and shortness of breath, which lead the patient to seek medical help.

Pathophysiology

A decrease in the number of RBCs can be traced to three conditions: (1) impaired production of RBCs, as in aplastic anemia and nutrition deficiencies; (2) increased destruction of RBCs, as in hemolytic or sickle cell anemia; or (3) massive or chronic blood loss. Some anemias are related to genetic problems in certain cultures (“Cultural Considerations”). It is important to remember that the general term anemia refers to a symptom or a condition secondary to another problem and is not a diagnosis in itself. Different types of anemia are discussed later in this chapter.

Etiology

Dietary Deficiencies. Iron, folic acid, and vitamin B₁₂ are all essential to the production of healthy RBCs. A deficiency of any of these nutrients can cause anemia. Pernicious anemia is associated with a lack of intrinsic factor in stomach secretions, which is necessary for absorption of vitamin B₁₂. See “Nutrition Notes” for more information.

Hemolysis. Hemolysis is the destruction, or lysis, of RBCs. Destruction of RBCs leads to a type of anemia called hemolytic anemia. This may be a congenital disorder, or it may be caused by exposure to certain toxins.

Other Causes. Thalassemia anemia is a hereditary anemia found in persons from Southeast Asia, Africa, Italy, and the Mediterranean islands. People with thalassemia do not synthesize hemoglobin normally. People with chronic disease also develop anemia (“Gerontological Issues”). Additional causes of anemia are discussed under the separate headings of aplastic and sickle cell anemias.

Signs and Symptoms

Symptoms of anemia include pallor, tachycardia, tachypnea, irritability, fatigue, and shortness of breath (Table 28.1). These symptoms occur because of the reduced number of functioning RBCs, with reduced ability to carry oxygen to tissues. In addition to these symptoms, the patient with pernicious (vitamin B₁₂) anemia may experience numbness of the hands or feet and weakness because vitamin B₁₂ is needed for normal neurologic function. Pernicious anemia is also associated with a sore, beefy red tongue. Patients with iron deficiency may have fissures at the corners of the mouth, an inflamed tongue (glossitis), and spoon-shaped fingernails.

Diagnostic Tests

A complete blood cell count (CBC) is done to determine the number of RBCs and WBCs per cubic millimeter. The size,
Because folic acid markedly decreases the occurrence of fetal neural tube defects such as spina bifida, women capable of becoming pregnant are advised to consume 400 mcg of synthetic folic acid daily from fortified foods or supplements in addition to the food folate furnished by a varied, balanced diet.

Vitamin B₁₂ is essential for the manufacture of DNA, RBCs, and for synthesis and maintenance of myelin, the fatty covering of nerves that facilitates rapid transmission of impulses. Vitamin B₁₂ requires a highly specific protein-binding factor called intrinsic factor, secreted by glands in the stomach, to protect vitamin B₁₂ from digestive enzymes and intestinal bacteria until the complex reaches the ileum where the vitamin is absorbed.

Vitamin B₁₂ is found in foods such as these:

• Meat, fish, shellfish, poultry
• Milk, cheese
• Eggs
• Vitamin B₁₂ fortified soymilk or tofu

A healthy person eating these foods regularly is not at risk of vitamin B₁₂ deficiency, but strict vegetarians may be at risk and have passed that risk to their breastfed infants. Pregnant and lactating vegan women’s diets should be evaluated carefully for deficiency of vitamin B₁₂.

Because the deficiency in this case is dietary, a dietary supplement is the treatment. Continued lack of vitamin B₁₂ can cause irreparable nerve damage.

Vitamin B₁₂ deficiency should be considered in a person being evaluated for dementia.

Gerontological Issues

Hemoglobin and hematocrit levels should remain unchanged in healthy older adults; anemia is usually brought on by an underlying medical condition that causes altered iron metabolism, deficiency of erythropoietin, or shortened life span of RBCs. Unfortunately anemia of chronic disease is often mistaken for iron-deficiency anemia; however, nutritional deficiencies and blood loss are common causes of iron-deficiency anemia.

Nutrition Notes

Understanding Common Nutritional Anemias

Nutritional deficiencies can produce some forms of anemia. Nutrients vital to the synthesis of RBCs include iron, folic acid, and vitamin B₁₂. Even if the cause of the anemia is dietary, other therapies may be used in addition to nutritional interventions.

Microcytic Anemia

Iron-deficiency anemia, the most common nutrient deficiency in the world, is characterized by smaller-than-normal RBCs. Insufficient intake of iron, excessive blood loss, or lack of stomach acid can lead to iron-deficiency anemia. Those at greatest risk of iron deficiency are women of childbearing age and young children. Even before obvious anemia is seen, cognitive abilities can be impaired.

Good sources of iron include the following:

• Meat, fish, and poultry contain 50 to 60% heme iron that is absorbed intact.
• Plant sources and the other 40% of iron in meat, fish, and poultry must be reduced by stomach acids to an absorbable form. Vitamin C assists in this conversion of iron in:
  • Cooked dark green leafy vegetables
  • Lima and navy beans
  • Dried fruits
  • Enriched, fortified, or whole-grain products

Techniques to enhance absorption of iron from nonheme sources include the following:

• Consuming foods rich in vitamin C with iron-rich foods
• Adding small amounts of meat, fish, or poultry to plant sources of iron
• Stewing acidic foods such as tomatoes in iron cookware that leeches iron from the pot

If iron supplements are given to treat iron deficiency, they should be continued for several months after hemoglobin and hematocrit levels return to normal to enable the body to rebuild iron stores.

Macrocytic Anemia

Folic acid or vitamin B₁₂ deficiencies produce anemias characterized by larger-than-normal RBCs.

Folic acid aids in the formation of DNA and heme, the iron-containing portion of hemoglobin and is particularly necessary for rapidly growing cells, including those in the gastrointestinal (GI) tract, blood, and fetal tissue. Many drugs including alcohol, anticonvulsants, and aspirin interfere with the use of folic acid and can lead to anemia.

Good food sources of folic acid include the following:

• Fortified flours, grains, cereals, wheat germ
• Liver
• Green leafy vegetables: asparagus, endive, lettuce
• Legumes: peanuts, dried peas, beans, and lentils

Because folic acid markedly decreases the occurrence of fetal neural tube defects such as spina bifida, women capable of becoming pregnant are advised to consume 400 mcg of synthetic folic acid daily from fortified foods or supplements in addition to the food folate furnished by a varied, balanced diet.

Vitamin B₁₂ is essential for the manufacture of DNA, RBCs, and for synthesis and maintenance of myelin, the fatty covering of nerves that facilitates rapid transmission of impulses. Vitamin B₁₂ requires a highly specific protein-binding factor called intrinsic factor, secreted by glands in the stomach, to protect vitamin B₁₂ from digestive enzymes and intestinal bacteria until the complex reaches the ileum where the vitamin is absorbed.

Vitamin B₁₂ is found in foods such as these:

• Meat, fish, shellfish, poultry
• Milk, cheese
• Eggs
• Vitamin B₁₂ fortified soymilk or tofu

A healthy person eating these foods regularly is not at risk of vitamin B₁₂ deficiency, but strict vegetarians may be at risk and have passed that risk to their breastfed infants. Pregnant and lactating vegan women’s diets should be evaluated carefully for deficiency of vitamin B₁₂.

Because the deficiency in this case is dietary, a dietary supplement is the treatment. Continued lack of vitamin B₁₂ can cause irreparable nerve damage.

Vitamin B₁₂ deficiency should be considered in a person being evaluated for dementia.
Therapeutic Measures

Treatment begins with elimination of contributing causes. Intake of the deficient nutrient can sometimes be increased in the diet or administered as a supplement (see “Nutrition Notes”). Changing cooking habits, taking dietary supplements, decreasing alcohol intake, and controlling chronic diarrhea can help correct folic acid deficiency. If symptoms of anemia are acute, a blood transfusion may be needed.

Nursing Process for the Patient With Anemia

DATA COLLECTION. Monitor hemoglobin and hematocrit levels and other laboratory studies as ordered and report any downward trend. Monitor responses to therapy, the patient’s fatigue level, and the patient’s ability to ambulate safely and perform activities of daily living (ADLs). Monitor degree of dyspnea and oxygen saturation, but be aware that at lower hemoglobin levels, oxygen saturation values may not be accurate. Assess for pallor in the skin and conjunctivae.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.

Possible nursing diagnoses are listed next along with outcomes and interventions.

Activity Intolerance related to tissue hypoxia and dyspnea

Expected Outcome: The patient will be able to tolerate activity as evidenced by the ability to complete ADLs with minimal assistance. The patient will have knowledge about conserving energy as evidenced by a verbal statement.

- Monitor vital signs to evaluate tolerance to activity. The patient experiencing activity intolerance may have tachycardia, increased respiratory rate, and decreased blood pressure with activity.

- If the pulse or respiratory rate increases more than 20% from baseline during activity, reduce the activity level. This is evidence that the activity is too strenuous and can result in increased hypoxia and dyspnea.

- Plan care to conserve energy after periods of activity. Balancing activities and rest periods assists the patient in conserving energy.

- Assist the patient with self-care activities as needed. Assisting with ADLs helps to decrease the amount of energy expended by the patient.

- Place articles within easy reach of the patient to reduce physiological demands on the body.

- Encourage the patient to limit visitors, telephone calls, and unnecessary interruptions to conserve energy.

- Administer oxygen as ordered to relieve dyspnea. The patient with anemia does not have enough hemoglobin to carry oxygen to vital organs.

- Assist with blood transfusion as ordered if hemoglobin levels are very low or symptoms are severe. A blood transfusion is a quick way to raise hemoglobin levels and to correct severe symptoms.

Imbalanced Nutrition: Less Than Body Requirements related to disease, treatment, or lack of knowledge about adequate nutrition

Expected Outcome: The patient will (1) have improved nutrition as evidenced by stable weight and stable hemoglobin and hematocrit and (2) will be able to appropriately select foods that will meet nutritional requirements.

- Consult a dietitian to provide diet instruction if the anemia is caused by a dietary deficiency.

- Teach the patient with folic acid deficiency that daily requirements can be met by including foods from each
food group at every meal. A balanced diet includes adequate amounts of folic acid.

- Instruct the patient to take the supplements as ordered by the health care provider (HCP). The patient should not stop taking the medication until the HCP advises him or her to do so.

- Instruct the patient that vitamin B₁₂ injections are given for lifetime with pernicious anemia because it is a chronic disease.

- Instruct the patient with iron deficiency about high-iron foods and the correct use of an iron supplement. An iron supplement should be taken with vitamin C to enhance absorption.

- Instruct the patient to notify the primary care provider of any side effects related to iron supplements such as nausea, diarrhea, constipation, and dark stools.

- Administer intramuscular iron injections by the Z-track method to avoid staining the injection site.

- Administer oral iron 1 hour before or 2 hours after meals to enhance absorption.

- Administer liquid supplements with a drinking straw to avoid staining the teeth.

Risk for Falls related to weakness and dizziness

**Expected Outcome:** The patient will remain safe from injuries related to a fall.

- Assess the patient at risk for falls using a fall risk assessment tool to determine risk.

- Assist the patient in changing positions slowly to decrease dizziness and risk of falls.

- Assist the patient with ambulation to prevent a fall.

- Protect the patient with pernicious anemia from injuries resulting from decreased sensation (e.g., take special care with heating pads and turning and positioning) because the ability to sense pain may be impaired.

Impaired Oral Mucous Membranes related to altered dietary status

**Expected Outcome:** The patient will have intact oral mucous membranes.

- Monitor condition of oral mucous membranes to detect changes.

- Provide good oral hygiene to keep the oral cavity clean and prevent infection.

- Encourage soft, bland foods, which are more tolerable until healing can occur.

- Instruct the patient to use a soft toothbrush for oral care because it is gentler until healing can occur.

EVALUATION. When successfully treated, the patient should be able to tolerate a normal level of activity without shortness of breath or excess fatigue. The patient should be able to explain the correct treatment plan and therapeutic measures for long-term prevention of problems, including dietary choices and supplements as well as self-care measures. The patient will remain free from injury, and the oral mucosa will be intact.

**Aplastic Anemia**

**Pathophysiology.** Aplastic anemia differs from other types of anemia in that the bone marrow becomes fatty and incapable of producing the needed numbers of RBCs. Also known as hypoplastic anemia, the cells that are produced are normal in size and shape, but there are not enough of them to sustain life. The resulting **pancytopenia** (reduced numbers of all formed elements from the bone marrow—RBCs, platelets, and WBCs) is the indicator that something is wrong with the bone marrow. Left untreated, aplastic anemia is almost always fatal.

**Etiology.** Aplastic anemia may be congenital—that is, the person is born with bone marrow incapable of producing the correct number of cells. Or it may be due to exposure to toxic substances such as industrial chemicals (e.g., benzenes and insecticides), chemotherapy medications, or use of cardiopulmonary bypass during surgery. Other causes include certain bacterial and viral infections, such as tuberculosis and hepatitis, or autoimmune disease.

**Signs and Symptoms.** The clinical features of aplastic anemia vary with the severity of the bone marrow failure. As with other anemias, early symptoms include progressive weakness, fatigue, pallor, shortness of breath, and headaches. As the disease progresses and the pancytopenia worsens, other symptoms, such as tachycardia and heart failure, may appear. Ecchymoses and petechiae appear on the skin because of the reduced platelet count (Fig. 28.1; also see Fig. 28.5). Blood may ooze from mucous membranes. Injection sites may progress from oozing to frank bleeding. There is often overt bleeding into vital organs. Infection occurs because of reduced WBCs. When aplastic anemia is left untreated, most patients die from infection or bleeding.

**Diagnostic Tests.** The diagnosis of aplastic anemia begins with a CBC. Usually all values are very low, with the occasional exception of the RBC count, in part because of the

---

Chapter 28  Nursing Care of Patients With Hematologic and Lymphatic Disorders  567

longer life span of RBCs. Eventually the RBCs are also depleted. If the patient is having gross bleeding internally or externally, the RBC level can drop rapidly and dramatically. The most definitive test is a bone marrow biopsy. Because the bone marrow is essentially dead, the result is often described as a “dry tap” in which pale, fatty, yellow, fibrous bone marrow is extracted instead of the red, gelatinous bone marrow normally seen. Not surprising, the more fatty and pale the marrow is, the more dysfunctional it is. Other diagnostic tests include total iron-binding capacity (TIBC) and serum iron level. It is common to find both of these levels elevated because the RBCs are not being produced and are using up the stores of iron in the production of hemoglobin.

THERAPEUTIC MEASURES. Early identification of the cause of the anemia and correction of the underlying problem are important to survival. Unfortunately, it is often difficult to determine the cause, and there is no way to reverse the damage already done. Aggressive supportive measures may be the only treatment. Most of these measures are aimed at prevention of infection and bleeding. Transfusions may be administered to replace deficient cells.

Today the most effective treatment for aplastic anemia is bone marrow transplantation (see “Patient Perspective”). Another common therapy is the administration of steroids to stimulate production of cells in the weakened bone marrow. Immunosuppressant agents may be given if an autoimmune disorder is the underlying cause. Occasionally the administration of hormones may work to increase the viability of the marrow. Steroid or other treatments may be tried before attempting a bone marrow transplant.

Bone Marrow Transplant

In June 2002, I took my daughter to the doctor for her sports physical. Later that day, I received a call telling me to take her to the university hospital immediately because she had a serious life-threatening illness. I kept telling myself and my husband that our small-town hospital must have made some sort of error. As it turned out, they had not. My daughter was diagnosed with aplastic anemia and needed a bone marrow transplant. I became obsessed with the illness, poring over every tidbit of medical information I could find. Sometimes I found myself out in the car unable to remember where I was going; sometimes I had to pull over because my eyes were filled with tears and I could no longer see.

My daughter was 16 at the time of her illness, yet it is the parents who sign consent forms and make the choices in care. When the chemotherapy was started and running through the IV tubing, I felt like grabbing the tubing and pinching it off, yelling, “I need more time to think about this decision,” but time was running out. Without a bone marrow transplant, she had about 8 months to live.

After transplantation, my daughter was in an isolation room for a month. I stayed with her every day, and at night I stayed at the inn that was attached to the hospital. If I was needed, I wanted to be no more than a minute away. I was one of the luckier parents because I had the financial means to manage this process. I thought about how horrible it would be if I had other children at home. Sometimes I would have such an urge to run away and escape from it all. I attended support groups that were held on the hospital unit. I got to know a lot of other parents with sick kids, and it became very upsetting to me at times. One day parents told me how well their child was doing; the next day I saw the child’s room empty and thought he must have gone home, only to find out later that he had died during the night. I wondered if my daughter would be next.

I look at my daughter now, 4 years later, alive and perfectly healthy, and I tell myself that I made the right choices for her. But she tells me that if it happens again, she will not go through chemotherapy. I wonder, is chemo worse than death?

In many treatment institutions, limited success is being obtained with the use of colony-stimulating factors, natural elements that can now be produced synthetically. (You can read more about these medications in Chapter 11.) For example, erythropoietin (Epogen) stimulates production of RBCs, and filgrastim (granulocyte colony stimulator [Neupogen]) stimulates production of WBCs. The major drawback to this type of therapy is the high cost. Many of the pharmaceutical manufacturers have patient access programs that help reduce the costs of these medications.

NURSING MANAGEMENT. Nursing care of patients with symptoms related to reduced RBCs was presented earlier in the “Nursing Process for the Patient With Anemia” section. If the patient’s platelet count is low (usually less than 20,000), the patient is placed on bleeding precautions (Box 28-1). If the WBC count is low, the patient must be protected from infection (Box 28-2).

BE SAFE!

BE VIGILANT! Watch carefully for even subtle signs of bleeding, such as early skin changes, or pink-tinged urine. Report findings before bleeding worsens.

Sickle Cell Anemia

PATHOPHYSIOLOGY. Sickle cell anemia is an inherited anemia in which the RBCs have a specific mutation that makes the hemoglobin in the red cells very sensitive to oxygen
changes. Any time a decrease in the oxygen tension is sensed, the cells begin an observable physical change from their usual spherical shape to a sickle or crescent shape (Fig. 28.2). Sickled cells are very rigid and easily cracked and broken. The abnormal shape also causes the cells to become tangled in the blood vessels and organs. The result is congestion, clumping, and clotting.

As RBCs are broken, the cellular contents spill out into the general circulation. The resulting increase in the bilirubin level causes jaundice. Gallstones (cholelithiasis) may develop because of the increased amounts of bile pigments. The spleen and liver may enlarge because of the increase in retained cells and cellular materials.

Because the cells are fragile, the life span of the RBCs in patients with sickle cell anemia is significantly decreased. Normal red cells live about 120 days. Sickled cells survive only about 10 to 20 days, an 80% to 90% decrease in cell survival.

**ETIOLOGY.** Sickle cell disease (SCD) is an autosomal recessive hereditary disorder. This means that if both parents pass
on the abnormal hemoglobin, the child will have the disease. If only one parent passes on the abnormal hemoglobin, the child will have the sickle cell trait and will be able to pass the trait (or the disease if the other parent is also affected) on to his or her child.

In the United States, sickle cell anemia is most often found in those of African or Eastern Mediterranean heritage. Worldwide, many persons residing in Asia, the Caribbean, the Middle East, and Central America are affected. Nearly 10% of African Americans have the sickle cell trait; 1 of every 500 African American infants born has inherited the two sets of abnormal genes needed to have the disease. Symptoms do not appear in infants until after the age of 6 months because up to that age, the infant is using hemoglobin manufactured during fetal life, which is not affected by the sickling process.

**SIGNS AND SYMPTOMS.** The sickling changes just described are a daily occurrence. The rapid return of the oxygen level to normal usually returns the cells to their normal shape.

Occasionally, the sickling process cannot be reversed, and the problem continues unabated. This sudden and severe sickling is called a sickle cell crisis. As more and more sickling occurs, the blood becomes sluggish and does not flow easily. It tends to collect in the capillaries and veins of chest and abdominal organs, as well as joints and bones, and can cause infarction (tissue necrosis resulting from lack of blood supply). Tissue necrosis causes pain, fever, and swelling.

Any condition that leads to decreased oxygenation can contribute to the development of a sickle cell crisis. Some examples include pneumonia with hypoxia, exposure to cold, diabetic acidosis, and severe infection. Sickle cell anemia presents problems for the patient who needs surgery. Anesthesia and blood loss during surgery and postoperative dehydration can trigger a crisis.

Common symptoms produced during sickle cell crises include severe pain and swelling in the joints, especially of the elbows and knees, as the sickled cells impede circulation. Abdominal pain is common with swelling of the spleen and engorgement of the vital organs. Hypoxia occurs as fever and pain increase, causing the patient to breathe rapidly. A male patient may have a continuous, painful erection (priapism) from impaired blood flow through the penis. Symptoms of renal failure are common as circulation is slowed and the kidneys become clogged with cellular debris.

Repeated crises and infarctions lead to chronic manifestations such as hand-foot syndrome, an unequal growth of fingers and toes from infarction of the small bones in the hands and feet (Fig. 28.3). Additional manifestations of SCD are shown in Figure 28.4.

The patient with sickle cell anemia has impaired quality of life. Often, strenuous exercise or more exotic activities, such as scuba diving, are impossible because of the risk of crisis. Crises may occur without any apparent cause. In general, crises last from 4 to 6 days. They may occur in cycles close together for a time and then become dormant for months to years. The cause of death in patients with sickle cell anemia is usually infection, stroke, or organ involvement.

**DIAGNOSTIC TESTS.** The most telling feature of SCD is a blood smear that shows sickle-shaped RBCs in circulation. The Sicklecx test is a screening test that shows sickling of RBCs when oxygen tension is low. Hemoglobin electrophoresis is a test used to determine the presence of hemoglobin (Hgb) S, the abnormal form of hemoglobin. Also, there is a decreased amount of hemoglobin, a lowered RBC count, an elevated WBC count, and a decreased erythrocyte sedimentation rate.

**THERAPEUTIC MEASURES.** Treatment depends on the severity of the disease. All patients should receive patient education to prevent crises and supportive care when crises occur. Some patients may be placed on low-dose oral penicillin to help prevent infections, decreasing the risk of crises.

During acute crises, the patient is admitted to the hospital. The nurse can anticipate that the patient will require sedation and analgesia for severe pain and blood transfusions to replace the sickled red cells lost by their being caught, crushed, and destroyed. Oxygen therapy decreases dyspnea caused by the anemia, and large amounts of oral and intravenous (IV) fluids are given to flush the kidneys of the byproducts of the many broken cells’ debris. Antibiotics are used to treat infection that may have triggered the crisis.

New treatments are being developed to treat SCD. Frequent blood transfusions, often monthly, are one of the newest treatment recommendations. However, frequent transfusions can cause high levels of iron to build up in the body.
Deferasirox (Exjade) is a medication that may be given to decrease the excess iron levels. Corticosteroids may reduce the need for analgesics and oxygen. Hydroxyurea (Droxia) is a drug that has been shown to decrease crises, but it can cause life-threatening side effects; it should also be used with caution in women of childbearing years because of the risk of birth defects. Patients may not adhere to hydroxyurea therapy because they don’t feel different; it may take months to years to make a difference in outcomes.

Bone marrow transplantation has shown promise in the treatment of SCD, although it is not without risk. In 2012, Johns Hopkins released data from a study of 17 patients with SCD who received bone marrow transplant. Eleven of the 17 patients had successful outcomes at the 2-year follow-up. Eight of the 11 transplants were half-matched transplants, meaning donor marrow came from parents, children, and siblings that were half-identical to the patient’s tissue. The transplant process is similar to the regimen for bone marrow transplant for cancer diagnoses. Because of the numerous blood transfusions throughout the life of a patient with SCD, antibodies have been acquired that make it difficult to administer donor marrow. Researchers continue to look for methods to improve the engraftment for transplants in the sickle cell population (Johns Hopkins, 2012).

NURSING PROCESS FOR THE PATIENT WITH SICKLE CELL ANEMIA.

Data Collection. In the patient in crisis, assess circulation in the extremities every 2 hours, including pulse oximetry, capillary refill, peripheral pulses, and temperature. Frequent pain assessment is also essential.

Nursing Diagnoses, Planning, and Implementation
Risk for Ineffective Tissue Perfusion related to sickled cells and infarction

EXPECTED OUTCOME: The patient will have adequate tissue perfusion as evidenced by the presence of peripheral pulses, warm extremities, urine output within normal limits, and a capillary refill time of less than 3 seconds.

- Encourage oral fluids, and assist the registered nurse (RN) to monitor IV fluids to dilute and aid in elimination of cell debris.
- Apply warm compresses as ordered to the painful areas, cover the patient with a blanket, and keep the room temperature above 72°F (22°C) to reduce the vasoconstricting effects of cold.
- Avoid cold compresses because they decrease circulation and increase the number of sickled cells caught in a painful area.
• Avoid restrictive clothing and raising the knee gatch (the adjustable joint in the hospital bed, which allows for the patient’s knee to be flexed and the legs supported). These can restrict circulation.

**Acute Pain related to tissue infarction**

**Expected Outcome:** The patient will state pain is controlled at an acceptable level at all times.

• Administer opioid analgesics such as morphine as ordered for acute pain. (Analgesics may be given intravenously or by use of patient-controlled analgesia.)
• Administer acetaminophen (Tylenol) to control fever.
• Avoid giving aspirin because it may increase acidosis, which can worsen the crisis.
• Encourage bedrest during the acute phase of the crisis to reduce oxygen demand.

**Evaluation.** If nursing care has been effective, the patient will state that he or she is comfortable, and will not have signs of poor circulation.

**Risk for Nonadherence to Treatment**

**Expected Outcome:** The patient will state reasons why treatment is important, and follow therapeutic regimen as prescribed.

• Assess patient and family’s understanding of rationale for treatment and expected effects. *Assessment of knowledge base should guide teaching.*
• Assess patient’s ability to obtain medication, including ability to make trips to laboratory and pharmacy. *One study looked at the patients enrolled in the North Carolina Medicaid program who were prescribed hydroxyurea between 1999 and 2008. Only 35% of the patients were adherent to the therapy. Reasons for nonadherence included difficulty in getting to the pharmacy monthly to fill the prescription and to the clinic for lab tests (Brandow & O’Brien, 2010).*
• Refer the patient and family for in-depth education as needed about treatment regimen. *Patients must understand therapy in order to adhere to it.*
• Refer the patient and family to a support group with others who have sickle cell anemia. *Support groups are a venue for sharing stories about personal experiences with the disease and to encourage each other to stay adherent to the medication.*

**Evaluation.** If interventions have been effective, the patient will state that he is comfortable, will have evidence of adequate circulation, will state understanding of importance of adhering to treatment plan, and will have fewer crises.

**PATIENT EDUCATION.** During remission, teach the patient how to prevent acute episodes. Advise the patient to a void tight-fitting clothing that restricts circulation. Also urge the patient to avoid strenuous exercise, which increases oxygen demand, as well as cold temperatures and smoking, which cause vasoconstriction. Alcoholic beverages can also trigger a crisis and should be avoided. Patients should never fly in unpressurized aircraft or undertake mountain climbing or other sports that can cause hypoxia. Encourage patients to get a pneumococcal vaccine and yearly flu vaccine. Encourage fluids to maintain hydration and reduce blood viscosity. Genetic counseling is important to prevent passing on the trait or disease to offspring. For more information, visit www.sicklecelldisease.org.

**Polycythemia**

**Pathophysiology and Etiology**

**Polycythemia** is really two separate disorders that are easily recognizable by similar characteristic changes in the RBC count. In both forms of polycythemia, the blood becomes so thick with an overabundance of RBCs that it closely resembles sludge. This thickness does not allow the blood to circulate easily. Laboratory tests show a hemoglobin level greater than 18 mg/dL, an RBC mass greater than 6 million, and a hematocrit of more than 55%.

Polycythemia vera (PV) is known as primary polycythemia. Most people with PV have a specific genetic mutation. In PV, the RBCs, platelets, and WBCs are all overproduced, and the bone marrow becomes packed with too many cells. As this overabundance of cells spills out into the general circulation, the organs become congested with cells and the tissues become packed with blood. The skin takes on a plethoric (dark, flushed) appearance from the buildup of red cells. The thick blood and excess platelets can cause thrombosis and occlusion of vessels. PV is usually found in patients over age 50.

In contrast, secondary polycythemia is the result of long-term hypoxia. Common coexisting conditions that may predispose a patient to secondary polycythemia include pulmonary diseases such as chronic obstructive pulmonary disease (COPD), cardiovascular problems such as chronic heart failure, living in high altitudes, and smoking. The body makes more RBCs in response to the low oxygenation associated with these conditions. Secondary polycythemia is a compensatory mechanism rather than an actual disorder.

**Signs and Symptoms**

A patient with PV commonly presents with hypertension, vision changes, headache, vertigo, dizziness, and ringing in the ears (tinnitus). Laboratory results show an increased level of all bone marrow components (RBCs, WBCs, platelets), which is called panmyelosis. Patients with extreme thrombocytopenia are also at risk for developing a bleeding disorder called acquired von Willebrand syndrome. The patient may have nosebleeds and bleeding gums, retinal hemorrhages, exertional dyspnea, and chest pain because of the increased pressure exerted by the excess cells. The patient usually has a dark, flushed complexion. Intense itching is related to excess mast cells (and, therefore, histamine) in the skin. Abdominal pain with an early feeling of fullness with meals occurs because of the enlarged liver and spleen. Nearly all of the symptoms in PV are due to the major problems of hypervolemia, hyperviscosity, and engorgement of capillary beds. Without treatment, patients with PV die of thrombosis or hemorrhage.

**WORD • BUILDING •**

polycythemia: poly—many + cyt—cells + emia—in the blood
Diagnostic Tests
Diagnosis of PV is made based on a CBC and bone marrow aspiration. A low level of erythropoietin is present, caused by negative feedback to the kidneys, where erythropoietin is made. The bone marrow or blood will also show the genetic mutation if it is present.

Therapeutic Measures
Treatment of PV takes place in two stages. The first stage is to decrease the hyperviscosity problem. The most common first-line treatment is therapeutic phlebotomy. Phlebotomy involves withdrawal of blood, which is then discarded. From 350 to 500 mL of blood are removed each time on an every-other-day basis, with the goal being a hematocrit of about 45%. This reduces the RBC level, and the patient usually feels more comfortable quickly. Repeated phlebotomies eventually cause iron-deficiency anemia, which in turn stabilizes RBC production; phlebotomies can then be reduced to every 2 to 3 months. Low-dose aspirin reduces the risk of blood clots.

The problem that remains is the increased WBC and platelet counts because phlebotomy does little to correct these overloads. Chemotherapeutic agents or radiation therapy, including radioactive phosphorus, may be used to suppress production of blood cells in some patients. Leukemia is a side effect of this therapy, so it is used only if the benefits outweigh the risks.

Nursing Management
Explain the phlebotomy procedure and reassure the patient that the treatment will relieve the most distressing symptoms. The procedure is the same as that used for donating blood. The patient should be active and ambulatory to help prevent thrombus formation. When bedrest is needed, passive and active range-of-motion exercises should be implemented. Monitor the patient for complications such as hypovolemia and bleeding.

If the patient has more advanced manifestations, such as an enlarged liver or spleen, offer several small meals each day so the patient will be more comfortable while still receiving adequate nutrition. A dietitian can be consulted to discuss ways to maintain good nutrition. If the patient is on drug therapy, monitor CBC and platelet counts.

Patient Education
Instruct the patient to drink at least 3 L of water daily to reduce blood viscosity. Encourage smoking cessation, avoidance of tight or restrictive clothing, and elevation of feet when resting to prevent impairment of circulation. Use of support hose when active also promotes circulation. If anticoagulants or antiplatelet agents are ordered, instruct the patient about side effects to watch for and the importance of routine laboratory tests. Routine bleeding precautions are implemented (see Box 28–1). Warn the patient to stop activities at the first sign of chest pain. Instruct the patient to report chest pain, increased joint pain, decreased activity tolerance, or fever, as well as signs of iron-deficiency anemia, such as pallor, weight loss, and dyspnea. Advise the patient to report any signs or symptoms of bleeding or thrombosis immediately.

HEMORRHAGIC DISORDERS

Disseminated Intravascular Coagulation

Pathophysiology
Disseminated intravascular coagulation (DIC) involves a series of events that result in severe hemorrhage.

As its name implies, this syndrome is a catastrophic, overwhelming state of accelerated clotting throughout the peripheral blood vessels. In a short period, all of the clotting factors and platelet supplies are exhausted, and clots can no longer be formed. This results in bleeding from nearly every bodily route possible. DIC is not a disease; it is a syndrome that develops secondary to some other severe physical problem. Once this deadly syndrome develops, the progression of symptoms is rapid.

Massive clotting in blood vessels leads to organ and limb necrosis. Organs most often affected include the kidneys and the brain, but other blood-engorged organs, such as the lungs, the pituitary and adrenal glands, and the GI mucosa, are commonly involved. DIC is usually acute in onset, although in some patients it becomes a chronic condition. The prognosis depends on early diagnosis and intervention and the severity of the hemorrhaging. DIC has a very high mortality rate.

Etiology
DIC can develop after any condition in which the body has sustained major trauma. The sources of trauma are varied and can include an overwhelming infection; obstetric complications such as abruptio placentae, amniotic fluid embolism, or a retained dead fetus; or cancer-related causes such as acute leukemia or lung cancer. Massive tissue necrosis found in severe crush or burn injuries may increase the risk of DIC. Tissue necrosis secondary to extensive abdominal surgery with leakage of the intestinal contents can also be related to DIC onset. Rarer causes of this condition have included heatstroke, shock, and poisonous snake bites, as well as fat embolism secondary to broken long bones.

Signs and Symptoms
Abnormal bleeding without a history of a serious hemorrhagic disorder is a cardinal sign of DIC. Early signs of bleeding include petechiae, ecchymoses (Fig. 28.5), and bleeding from venipuncture sites. Bleeding may progress to IV sites, skin tears, surgical sites, incisions, and the GI tract and oral mucosa. Joints become painful and enlarged if bleeding into the joints occurs. All of these signs and symptoms may occur at the same time. Massive bleeding may also be accompanied by nausea, vomiting, dyspnea, oliguria, convulsions, coma, shock, major organ system failure, and severe muscle, back, and abdominal pain.

Diagnostic Tests
Initial laboratory findings in DIC include a prolonged prothrombin time (PT) and partial thromboplastin time (PTT), decreased platelet count, and increased evidence of fibrin degradation products (Table 28.2). A decrease in hemoglobin is the result of spilled hemoglobin from the increased numbers of broken red cells. Blood urea nitrogen (BUN) and serum creatinine levels may also be increased.
Therapeutic Measures

Effective treatment of DIC depends on early recognition of the condition. Treatment is first aimed at correcting the underlying cause. Additional treatment consists of supportive interventions, including administration of blood, fresh frozen plasma, platelets, vitamin K, and the infusion of cryoprecipitate (containing clotting factors) to support hemostasis. IV heparin may be used to help prevent initial microembolization and may also be used for chronic DIC cases. Additional therapies are being investigated.

Nursing Management

Care of the patient with DIC is a nursing challenge. Early intervention requires vigilance in recognizing and reporting signs of bleeding. In addition to supportive care, focus on the prevention of further bleeding episodes. Care should be taken to avoid any trauma that might cause bleeding. Be careful not to dislodge clots from any site because another clot may not form, and the patient will hemorrhage. See Box 28-1 for bleeding precautions.

Patient Education

Because a patient with DIC is often cared for in the intensive care unit, there are many opportunities for patient and family teaching. Explain all diagnostic tests to the patient if he or she is alert. If not, keep the family informed. A large part of family education is preparing the family for what the patient may look like in terms of bleeding and bruising, as well as specific equipment that may be in place, such as IV lines, a nasogastric (NG) tube, and an indwelling urinary catheter. It may be helpful to enlist the aid of social workers, chaplains, and other members of the health care team to help support the family.

CRITICAL THINKING

Mrs. Johns

1. What data will you collect as you care for Mrs. Johns?
2. What treatment do you anticipate?
3. What concerns is Mrs. Johns likely to have?
4. Mrs. Johns is to receive IV fresh frozen plasma 300 mL over 30 minutes. How many milliliters per hour should be set on the IV controller?
5. What members of the health team should you anticipate collaborating with?

Suggested answers are at the end of the chapter.

Idiopathic Thrombocytopenic Purpura

Pathophysiology and Etiology

Acute idiopathic thrombocytopenic purpura (ITP) results from increased platelet destruction by the immune system. Any time platelet numbers are reduced, the risk for bleeding increases. Acute ITP usually affects children between ages 2 and 6, whereas chronic ITP mainly affects adults over age 60.

• WORD • BUILDING •

idiopathic thrombocytopenic purpura: idio—unknown + pathic—disease + thrombo—clot + cyto—cell + penic—lack + purpura—hemorrhage in the skin
Acute ITP usually occurs after an acute viral illness such as rubella or chickenpox. Hepatitis C virus and human immunodeficiency virus (HIV) can also be triggers. It may be drug-induced or associated with pregnancy. ITP is believed to be related to an immune system dysfunction. Antibodies responsible for platelet destruction have been found in nearly all diagnosed patients.

**Signs and Symptoms**

ITP produces clinical changes that are common to all forms of thrombocytopenia: petechiae, ecchymoses, and bleeding from the mouth, nose, or GI tract. Bleeding may occur in vital organs, such as the brain, which may prove fatal. In the acute type, onset may be sudden and without warning, causing easy bruising, nosebleeds, and bleeding gums. Onset of chronic ITP is usually insidious.

**Diagnostic Tests**

A platelet count of less than 20,000/mm³ and a prolonged bleeding time suggest ITP. The greatly decreased platelet level places the patient at serious risk for hemorrhage. Examination of platelets under the microscope shows them to be small and immature. Anemia may be present if there has been a bleeding episode. If a bone marrow aspiration is performed, the results show an adequate amount of the precursor cells for platelets, the megakaryocytes. However, instead of the 7- to 10-day life span that platelets usually have, these immature platelets have a life span of just a few hours.

**Therapeutic Measures**

The goal of treatment is to have an adequate (if not normal) platelet count and no bleeding. Most cases of acute ITP resolve spontaneously without treatment. Initial treatment, if needed, often involves the administration of steroids. The purpose of the steroids is to prolong the life of the platelets by decreasing immune activity. In acute situations, immune globulin may be given to quickly increase the blood count. Some patients receive chemotherapeutic drugs. The spleen may be removed because it is the primary site of platelet destruction. Often the patient undergoing splenectomy has tried all other courses of treatment unsuccessfully and may be having bleeding episodes. Acute bleeding episodes are treated with transfusions of blood, platelets, and vitamin K.

**Nursing Care**

Care for the patient with ITP is the same as any patient with a bleeding disorder. See Box 28-1 for bleeding precautions. Teach the patient to watch for and report signs and symptoms of bruising and bleeding (Box 28-3, “Patient Education”). The patient should avoid trauma and restrict activity during severe episodes.

**Hemophilia**

Hemophilia is a group of hereditary bleeding disorders that result from a severe lack of specific clotting factors. The two most common are hemophilia A (classic hemophilia) and hemophilia B (Christmas disease). Von Willebrand’s disease is another related bleeding disorder, but it represents a minority of cases and is not discussed in this chapter.

**Pathophysiology**

Recall that many different clotting factors make up the clotting mechanism. Hemophilia A accounts for 80% of all types of hemophilia and results from a deficiency of factor VIII. Hemophilia B is a factor IX deficiency; about 15% of people with hemophilia have this type. The severity and prognosis of hemophilia depend on the degree of deficiency of the specific clotting factors. Mild hemophilia has the best prognosis because it does not cause spontaneous bleeding and joint deformities like severe hemophilia can.

After an injury, the person with hemophilia forms a platelet plug (which differs from a clot) at the site of an injury as would normally be expected, but the clotting factor deficiency keeps the patient from forming a stable fibrin clot. Continued bleeding washes away the platelet plug that initially formed. Contrary to popular myths, people with hemophilia do not bleed faster and are not at risk from small scratches.

**Etiology**

Hemophilia A and B are inherited as X-linked recessive traits. This means that the female carrier (daughter of an affected father) has a 50% chance of transmitting the gene to each son or daughter. Daughters who receive the gene are carriers, and sons who receive the gene are born with hemophilia. It is technically possible for daughters to be affected with hemophilia, although it is rare.

**Signs and Symptoms**

Bleeding occurs as a result of injury or, in severe cases, spontaneously (unprovoked by injury). Bleeding into the muscles and joints (hemarthrosis) is common and can cause acute pain. Severe and repeated episodes of joint hemorrhage cause joint deformities, especially in the elbows, knees, and ankles, which decrease the patient’s range of motion and ability to walk.

---

**Box 28-3 Patient Education**

**Signs and Symptoms of Bleeding**

Notify your health care provider if the following occur:

- Easy bruising of skin
- Petechiae (small red spots on skin)
- Blood in urine
- Black tarry stools
- Bleeding from nose or gums
- Increase in vaginal bleeding
- New onset of painful joints

---

**WORD BUILDING**

- hemophilia: hemo—blood + philia—to love
- thrombocytopenia: thrombocyte—platelet + penia—lack
- hemarthrosis: hem—bleeding + arthr—joint + osis—condition
Chapter 28  Nursing Care of Patients With Hematologic and Lymphatic Disorders

In mild hemophilia, excessive bleeding is usually associated only with surgery or significant trauma. However, once a person with mild hemophilia begins to bleed, the bleeding can be just as serious as that of the patient with a more severe form.

The patient with moderate hemophilia has an occasional bout of spontaneous bleeding. In severe hemophilia, spontaneous bleeding occurs more frequently. It would be possible for the patient to develop hemarthrosis or bleeding into the brain without any precipitating trauma. Severe episodes can produce large subcutaneous and deep intramuscular hematomas. Major trauma can cause bleeding so severe that it becomes life threatening.

Another unfortunate problem related to hemophilia treatment is the frequent need to replace clotting factors and other blood products. Before 1986, blood banks and other centers did not routinely test for human immunodeficiency virus (HIV) antibodies. Depending on the patient’s age and frequency of treatment, many patients may have been exposed to HIV or hepatitis. Blood banks and pharmacies have checked their blood supplies for the presence of HIV since 1986. Today, the plasma proteins are artificially created or thoroughly cleansed to prevent transmission of disease.

**Diagnostic Tests**

Laboratory data reveal a prolonged PTT. The various clotting factor levels are measured to determine which is missing. Once the missing factor is identified, the type of hemophilia is determined and necessary treatments can be implemented. In some cases of mild hemophilia, a surgical procedure or trauma is the first time a bleeding problem is noticed.

**Therapeutic Measures**

Hemophilia is not curable. However, treatment advances have improved outcomes, and many patients can now live a normal life span. Treatment is aimed at preventing or controlling bleeding episodes by administering the missing clotting factors. Mild hemophilia A may be treated with injection or nasal inhalation of desmopressin (DDAVP, antidiuretic hormone), which can stimulate the body to release more clotting factors. More severe hemophilia A is treated with factor VIII; hemophilia B is treated with factor IX. Each is available in a freeze-dried powder that is reconstituted with water and administered intravenously. The newest treatment employs factors made using recombinant DNA technology without the use of any human blood products. Blood transfusions are uncommon but may be necessary after severe trauma or surgery.

Complications occur when therapy is started too late. Minor trauma typically needs to be treated with at least 72 hours of added clotting factors; major traumas and surgeries may require up to 14 days of added factors to prevent sudden bleeding. Health care workers should pay careful attention to the patient who says that bleeding is starting even when no outward signs are evident. The patient usually knows from experience if bleeding is starting. If treatment is delayed at this time, the results can be disastrous. Some patients with severe disease are treated prophylactically to prevent bleeding.

**Nursing Process for the Patient With Hemophilia**

**DATA COLLECTION.** Because a major goal is prevention of bleeding episodes, assess the patient and family for knowledge of the disease and its treatment and understanding of preventive measures. Most patients care for themselves at home, starting their own IVs and administering treatment independently. Hospitalization is needed only for surgery or major trauma. During an acute episode of bleeding, monitor hemoglobin and hematocrit carefully. Monitor factor VIII or IX levels to determine if factor replacement has reached adequate levels. Monitor vital signs for falling blood pressure and rising pulse rate, which are signs of hypovolemic shock. All body systems are assessed for signs of bleeding (Box 28-3). Perform a pain assessment using the WHAT’S UP? format.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

**Acute Pain related to bleeding into tissues**

**EXPECTED OUTCOME:** The patient’s pain will be controlled as evidenced by verbalization that pain is relieved to a satisfactory level within a specified time frame depending on medication and route of intervention.

- Have the patient report the location, intensity, and quality of the pain. Assessment provides the caregiver with data that can be used to develop a treatment plan.
- Administer opioids as prescribed, including patient-controlled analgesia. Analgesics are the primary way to manage moderate to severe pain.
- Avoid the administration of intramuscular injections because of the risk of bleeding into the muscle.
- Reassess the level of pain after administration of analgesia to determine the effectiveness of the treatment ordered. IV medications will work almost immediately; oral medications may take 30 to 60 minutes.
- Monitor sedation and respiratory status of the patient receiving opioids for pain. Opioids depress the respiratory center of the brain.

**Risk for Bleeding related to factor deficiencies**

**EXPECTED OUTCOME:** The patient will experience no signs or symptoms of bleeding. The patient will verbalize understanding of bleeding precautions.

- Instruct the patient on bleeding precautions (see Box 28-1).
- Identification of signs of bleeding will promote early intervention to prevent injury.
- Assist with administration of factor concentrates, fresh frozen plasma, cryoprecipitate, blood, or a combination of these as ordered to treat acute episodes of bleeding. See Chapter 27 for transfusion of blood products.
- Apply ice or pressure on bleeding sites to help slow bleeding.
- Avoid intramuscular, subcutaneous, or rectal medications. These routes can cause bleeding into tissues.
- Instruct the patient that preventive care will be needed if surgery or dental procedures are needed. These invasive procedures can be life-threatening events for the patient with hemophilia.
Risk for Ineffective Self Health Management related to deficient knowledge

**EXPECTED OUTCOME:** The patient will be able to manage self-care requirements as evidenced by verbalization of understanding/demonstration of the treatment regimen.

- Assess knowledge base and determine readiness to learn and incorporate new information. *Each patient is unique in the way he or she learns new information.*
- Instruct the patient on ways to prevent bleeding and recognition of signs and symptoms of bleeding (see Boxes 28-1 and 28-3). *Identification of signs of bleeding will promote early intervention to prevent injury.*
- Instruct the patient to obtain emergency care in the event that bleeding occurs. *Intervention is critical for survival of an acute bleeding episode.*
- Instruct the patient to administer factor treatments at home. *Treatment can often be administered at home and can be given more promptly if a trip to the emergency department is not needed.*
- Instruct patients and families on the community services and hemophilia treatment centers available to the patient. *These centers are nationwide and coordinate care for patients with hemophilia.*
- Instruct the patient that the approach to care is multidisciplinary in nature and includes social services, dental, rehabilitation, nursing, financial, and medical needs. *These are all areas that have an impact on the care of the patient with hemophilia.*

**EVALUATION.** If interventions have been effective, the patient will be comfortable, and bleeding will be prevented or complications minimized. The patient and family will be able to state appropriate measures to prevent and treat bleeding episodes. The patient will be knowledgeable about the resources available to cope with the diagnosis of hemophilia.

**DISORDERS OF WHITE BLOOD CELLS**

**Leukemia**

The term *leukemia* literally means “white blood.” It was first identified in 1845 when the blood of victims was examined and found to have an excess of “colorless” cells.

**Pathophysiology**

Leukemia is a malignant disease of the WBCs that affects all age groups. The immature WBCs (blast cells) generate in an explosive fashion in the bone marrow, lymph tissue, and spleen. The cells are abnormal and unable to effectively fight infection. So many abnormal cells develop and are dumped into the peripheral circulation that they tend to collect in the body tissues and organs, especially where circulation is sluggish. Areas especially prone to infiltration with immature WBCs are the oral mucosa, anus, sinuses, and lungs. At the time of diagnosis, these areas are often inflamed, painful, and infected. It is common for patients to be diagnosed only after experiencing an infection that does not clear up easily with treatment.

As the disease progresses, the bone marrow continues to produce large numbers of the useless cells; the peripheral circulation is filled with them, and the bone marrow is packed with blast cells. Because so many of the blood stem cells are being used to make defective white cells, production of most other normal cells is impossible. The patient becomes anemic because of the lack of RBC production, and bleeding becomes a problem as fewer and fewer platelets are manufactured. But most importantly, even though the WBC count is very high, there are few normal, mature, and active white cells with which to fight infection. Thus, the patient often begins to have raging infections that do not respond to antibiotics. Without treatment, leukemia leaves the patient unable to fight infection, unable to control bleeding, and in a downward spiral of fatigue and anorexia. Untreated leukemia is almost always fatal.

**Classifications**

- Leukemias are classified as either acute or chronic and either lymphoid or myeloid. Symptoms of the acute leukemias begin suddenly, and the patient is very sick, whereas chronic leukemias develop slowly and patients can be surprised by the diagnosis because they feel well. Lymphoid leukemias affect the lymphocytes. Myeloid leukemias originate in the stem cells of the bone marrow that develop into monocytes, granulocytes, erythrocytes, and platelets. The most common leukemias are discussed next.

**ACUTE LEUKEMIAS.** Acute lymphocytic leukemia (ALL) is the most common cancer in children and involves abnormal growth of the lymphocyte precursors (lymphoblasts). Acute myelogenous (myeloblastic) leukemia (AML) usually affects people over age 60 and has a poor prognosis. The patient with acute leukemia may present with sudden onset of high fever, abnormal bleeding from the mucous membranes, petechiae, ecchymoses, and easy bruising after minor trauma. Death usually results from infection.

**CHRONIC LEUKEMIAS.** Chronic lymphocytic leukemia (CLL) predominantly affects the B and T lymphocytes and usually occurs in adults. Chronic myelogenous leukemia (CML) is characterized by the Philadelphia chromosome and occurs most often in older adults.

Chronic leukemia usually develops in a three-phase process. The first, insidious phase is characterized by anemia and mild bleeding abnormalities. During this phase, the patient often feels well and is not even aware of being sick. After a time, generally years, the disease progresses to the accelerated and acute phases, in which the scenarios are similar to the events seen in acute leukemias. Chronic leukemia is almost always fatal; the average survival time is 3 to 5 years after onset of the chronic phase and 3 to 6 months after onset of the acute phase. With advances in treatments, however, it is not uncommon to encounter patients who have been living with chronic leukemia for 10 years or more.

**Etiology**

The cause of leukemia is unknown. Risk factors are thought to include certain viruses because remnants of viruses have...
been found in leukemic cells. Genetic and immunological factors are often involved. For example, persons with Down syndrome are more likely to develop leukemia. Exposure to radiation is believed to be a factor, in part because radiologists have been found to have a higher than average development of leukemia. Some patients have developed leukemia after being treated for another unrelated malignancy using radiation or chemotherapy. Researchers have noted the higher occurrence rate of leukemia in persons who lived through the Hiroshima and Nagasaki atomic bombings during World War II. Water polluted with benzenes and other chemicals have high fevers from infection. Ecchymosis or petechiae may result from thrombocytopenia. There is no single clear-cut cause for the development of leukemia.

**Signs and Symptoms**

Symptoms are similar for all types of leukemia and include low-grade fever caused by infection and pallor, weakness, lethargy, shortness of breath, and malaise caused by anemia. These symptoms may be present weeks or months before the appearance of other symptoms. The patient also may have fatigue, tachycardia, palpitations, and abdominal pain. Sternal pain and rib tenderness may result from crowding of bone marrow. If the leukemia has invaded the central nervous system, the patient may experience confusion, headaches, and personality changes. During the acute phase the patient may have fevers from infection. Echymosis or petechiae may result from thrombocytopenia.

**Diagnostic Tests**

Although a simple CBC often points toward the diagnosis, only bone marrow aspiration can show the degree of proliferation of the malignant WBCs and confirm the diagnosis of leukemia. The CBC may also show a decrease in the numbers of platelets, RBCs, and mature WBCs. A lumbar puncture helps determine if the central nervous system is involved. Genetic analysis of the peripheral blood and bone marrow may show the presence of the Philadelphia chromosome in patients with CML.

**Therapeutic Measures**

**CHEMOTHERAPY.** Systemic chemotherapy aims to eradicate the leukemic cells and induce a remission. Remission means that the bone marrow is free to produce normally occurring cells in normal proportions without production of the immature WBCs. The type of chemotherapy used varies with the type of leukemia and the level of involvement.

The overall goal of the initial treatments is to get the patient to a state of remission. Occasionally, partial remission is achieved when everything looks good except for an occasional leukemic cell seen in the bone marrow. Remission is not the same as a cure.

There are four phases to the treatment of leukemia: induction, intensification, consolidation, and maintenance. Induction is the period in which an attempt is made to get the patient into remission. This first phase is difficult because chemotherapy is given in very high doses and on an aggressive timetable. Often the patient becomes quite ill from complications of the treatment. The patient may become depressed because the treatment seems worse than the disease at this stage. The nurse must help the patient deal with anemia, thrombocytopenia, and leukopenia, as well as other side effects (Table 28.3; also see Box 28-2 and Chapter 11).

If the first remission is accomplished, the other phases of treatment are begun. Intensification is similar to the initial induction phase, using the same drugs at even higher doses. The next phase, consolidation, is used to ensure that all leukemic cells have been eradicated from the body. Finally, the patient graduates to maintenance therapy in which the patient is kept free of leukemic cells and in remission for a period of years (and hopefully a lifetime). This requires years of continued chemotherapy treatments, often on a monthly basis.

**RADIATION THERAPY.** Radiation therapy is sometimes used in addition to chemotherapy for initial treatment of leukemia. It may be directed at the entire body or at specific areas where leukemic cells are collecting.

**BONE MARROW TRANSPLANT.** Bone marrow transplant (BMT) is sometimes used to treat leukemia. Preparation for BMT includes high-dose chemotherapy and/or total body irradiation. The goal is to destroy all of the patient’s malignant bone marrow and then, at the last possible moment, replace it with a donor’s clean and healthy bone marrow (allogenic transplant). Another type of bone marrow transplant, known as an autologous transplant, uses the patient’s own diseased bone marrow, which is harvested, chemically treated and cleaned, stored, and later reinfused. Transplanted bone marrow is given to the patient like a blood transfusion; typically through a central line placed in the chest. Once infused into the bloodstream, the new marrow travels to the bones, where, ideally, it will begin to grow and function normally. Bone

NURSING CARE PLAN for the Patient With Leukemia

**Nursing Diagnosis:** Risk for Injury (infection, bleeding) related to pancytopenia

**Expected Outcomes:** The patient will be free from injury and infection as evidenced by temperature within normal limits and no signs or symptoms of bleeding. Signs and symptoms of infection or bleeding will be reported promptly.

**Evaluation of Outcomes:** Is the patient free from infection and bleeding, or are problems reported so that quick intervention can prevent further complications?

**Intervention**

- Monitor vital signs every 4 hours and as needed. **Rationale** Elevated temperature is a sign of infection. Falling blood pressure and elevated pulse rate may indicate sepsis or blood loss. **Evaluation** Are vital signs stable?

- Monitor patient for swelling, redness, purulent drainage. **Rationale** These are signs of infection and should be reported promptly. **Evaluation** Are signs of infection present?

- Protect patient from sources of infection (see the “Evidence-Based Practice” box; also see Box 28-2). **Rationale** Patient is at risk for infection because of ineffective WBCs. **Evaluation** Are precautions being observed to prevent infection?

- Observe for tarry stools, petechiae, ecchymosis (Box 28-3). **Rationale** These are signs of bleeding and should be reported promptly. **Evaluation** Are signs of bleeding present?

- Protect patient from injury that could cause bleeding (see Box 28-1). **Rationale** Patient is at risk for bleeding because of reduced platelet count. **Evaluation** Are precautions being observed to prevent injury and bleeding?

**Nursing Diagnosis:** Fatigue related to decreased red cell count and oxygenation and effects of treatments as evidenced by patient statement of lack of energy, inability to participate in desired activities

**Expected Outcome:** The patient’s fatigue will be controlled at a level that is acceptable to the patient as evidenced by patient ability to participate in activities that are important to him or her.

**Evaluation of Outcome:** Is patient able to identify and participate in activities as desired?

**Intervention**

- Assess fatigue using the WHAT’S UP? format. **Rationale** A good assessment establishes a baseline and aids in planning. **Evaluation** Is fatigue present? To what degree?
### Intervention
Assist patient to identify activities that are important to him or her (e.g., ADLs, attending a child’s wedding, taking a trip). Assist in setting goals to work toward the desired activity. **Rationale** If the patient cannot do everything he or she wishes, it may help to focus on the most important things. **Evaluation** Can patient identify important activities? What are they? How can the nurse assist the patient to reach activity goals?

**Intervention** Encourage a balanced diet. Contact dietitian as needed. **Rationale** Poor nutrition contributes to fatigue. **Evaluation** Is patient eating a balanced diet? Is weight stable?

**Intervention** Allow periods of rest between activities. **Rationale** Any activity (ADL, x-rays, even talking) can increase fatigue. **Evaluation** Does patient state feeling rested on awakening? Is medication needed?

**Intervention** Provide for ADLs when patient is unable to do so independently. **Rationale** Extreme fatigue may prevent the patient from participating in self-care. **Evaluation** Does patient need total assistance?

### Nursing Diagnosis: Impaired Oral Mucous Membranes
related to chemotherapy and pancytopenia as evidenced by bleeding, ulcerations, statement of pain, difficulty eating.

### Expected Outcomes:
The patient’s oral mucous membranes will remain intact as evidenced by pink, moist, smooth tissue without ulceration. The patient will be able to eat a balanced diet.

### Evaluation of Outcomes:
Are oral mucous membranes intact, without lesions? Is patient eating a balanced diet?

**Intervention** Assess mouth daily for redness, edema, and lesions. **Rationale** Routine assessment helps identify problems early so treatment can be implemented. **Evaluation** Are mucous membranes intact?

**Intervention** Encourage adequate nutrition and fluids. **Rationale** Poor nutrition and dehydration increase the risk of oral lesions. **Evaluation** Is patient eating and drinking?

**Intervention** Encourage patient to brush teeth after meals with a soft toothbrush. If irritation is severe or if the patient is at risk for bleeding, use swabs or sponge Toothettes instead of a toothbrush. **Rationale** Brushing the teeth controls tooth and gum disease; a toothbrush may be too harsh if the patient is at risk for bleeding. **Evaluation** Is mouth care being provided after meals? Is mouth care irritating? Are alternative methods needed?

**Intervention** Avoid use of lemon-glycerin swabs for mouth care. **Rationale** Lemon-glycerin swabs are drying to oral mucosa. **Evaluation** Are products used appropriate?

**Intervention** Obtain an order for a mouthwash containing diphenhydramine (Benadryl). Obtain an order for a topical anesthetic if mouth is very inflamed and painful. **Rationale** Diphenhydramine reduces inflammation; anesthetics reduce pain. **Evaluation** Does mouthwash soothe pain?

**Intervention** Encourage the patient to avoid smoking, alcohol, acidic food or drinks, extremely hot or cold foods and drinks, and commercial mouthwash. **Rationale** These things can be irritating to the mucosa. **Evaluation** Does patient state understanding of things to avoid?

### GERIATRIC
**Intervention** Advise patient to remove dentures for cleaning and at bedtime. **Rationale** Dentures left in for long periods can impair circulation and increase risk of lesions. **Evaluation** Are oral mucous membranes intact?
MULTIPLE MYELOMA

Multiple myeloma is a deadly cancer of the plasma cells in the bone marrow. When the disease is caught in its early stages, treatment can prolong life by 3 to 5 years. More important, early detection can decrease the amount of pain and disability due to bony destruction and pathological fractures. Unfortunately, almost half of patients die within the first 3 months after diagnosis because of the silent and deadly nature of the disease; another 40% of patients die within 2 years after diagnosis. Multiple myeloma currently has a 45% survival rate at 5 years (www.cancer.net/cancer-types/multiple-myeloma/statistics, 2012). Multiple myeloma most often affects men aged 50 to 70.

Pathophysiology

In this disorder, cancerous plasma cells in the bone marrow begin reproducing uncontrollably. These cells infiltrate bone tissue all over the body and produce hundreds of tumors that begin to devour the bone tissue. X-ray examination may show holes in the bones forming a Swiss cheese pattern (Fig. 28.6). As more and more of these holes are formed, the integrity of the bone is compromised and weakened. Multiple myeloma usually affects the bones of the skull, pelvis, ribs, and vertebrae.

As the disease progresses, plasma cells infiltrate the major organs, including the liver, spleen, lymph nodes, lungs, adrenal glands, kidneys, skin, and GI tract. Because the diagnosis is usually made only after widespread invasion of the bones is well under way, the prognosis for patients with this disease is poor. Although the overall result of the disease is the devastating destruction of the bone and widespread osteoporosis, death is often from sepsis.
Etiology
The cause of multiple myeloma is unknown. Research suggests genetics may be one factor. People who work in rubber, leather, farming, and petroleum industries are more likely to develop multiple myeloma. Obesity, exposure to radiation, and long-term exposure to hair dyes also increase risk.

Signs and Symptoms
Skeletal pain is the most common complaint. The patient may describe the pain as constant severe back pain that increases with exercise or movement or as pain in the ribs. Other signs and symptoms include achiness of the long bones, joint swelling and tenderness, low-grade fever, and general malaise. Sometimes there is evidence of early peripheral neuropathy secondary to vertebral collapse and spinal cord compression. The patient may be unable to feel the true temperature of bath water and be burned or may be unable to feel wounds and infections on the feet. In more severe cases of cord compression, the patient may lose control of bladder and bowels. This is a true oncological emergency. Prompt emergency treatment is needed to keep the patient from becoming paralyzed.

Occasionally, patients have pathological fractures of the long bones. These are fractures that occur with no trauma, such as the person who breaks a leg just turning over in bed or breaks a rib while sneezing. In advanced disease there is anemia, weight loss, thoracic spinal deformities from multiple rib destruction, and a loss of height because of pathological fractures and compacting of the vertebrae.

Because calcium is mobilized from the bones and into the blood, the patient is at risk for hypercalcemia. Signs and symptoms of hypercalcemia include anorexia, nausea, vomiting, mental changes (especially confusion), seizures, weakness, and fatigue. Kidney stones may result as the excess calcium passes through the kidneys.

Patients are susceptible to infection because of compromised immune function. Pneumonia is a common finding in patients with multiple myeloma. They may develop anemia because of bone marrow dysfunction and reduced erythropoietin formation by diseased kidneys. Risk for bruising and bleeding occurs due to thrombocytopenia.

Patients often develop kidney failure because the filtering capacity of the kidney becomes blocked by calcium. Other factors include recurrent infections and deposits of myeloma cells in the kidneys.

Diagnostic Tests
A CBC shows moderate to severe anemia. The WBC count may show an increase in the number of white cells secondary to infection. Blood and urine studies are positive for M-type globulins (called Bence-Jones proteins when found in the urine) in 40% of patients. X-ray examinations or magnetic resonance imaging (MRI) may show changes in the lungs and diffuse osteoporosis in bones not already riddled with holes. Bone marrow biopsy is done to confirm the diagnosis and determine the stage of the disease.

Blood chemistries often show an increased amount of calcium in the blood. Hypercalcuiuria results when the calcium released out of the bones is flushed out in the urine. An IV pyelogram may be done to see how much calcium is collecting in the kidneys. A 24-hour urine collection is done to evaluate protein excretion.

C-reactive protein (CRP) is elevated in multiple myeloma; it is believed that the CRP actually promotes the cancer cells’ proliferation and protects them from the effects of chemotherapy agents. Measurement of CRP helps determine prognosis. Elevated CRP levels are also associated with increased fatigue.

Therapeutic Measures
Long-term treatment of multiple myeloma consists of a two-pronged approach: (1) managing the disease and (2) managing the symptoms. To manage the disease, corticosteroids (prednisone or dexamethasone) and oral or IV chemotherapy agents are given. Thalidomide may be given to slow the progression of the disease. Lenalidomide (Revlimid) is chemically similar to thalidomide but has fewer side effects. The goal of drug therapy is to suppress plasma cell proliferation, which then helps decrease the amount and speed of bone destruction.

Another medication for multiple myeloma is bortezomib (Velcade). Bortezomib is a proteasome inhibitor that inhibits enzymes to disrupt cancer cell growth and survival.

Another option is high-dose chemotherapy combined with stem cell transplantation. Donor stem cells can be used, or a patient’s own peripheral stem cells can be removed and reinfused. These stem cells can then differentiate into new, healthy cells. Methods of cleaning the cells to prevent contamination with malignant cells are being researched.

The second approach is control of symptoms. The patient is monitored for signs and symptoms of hypercalcemia, hyperuricemia, dehydration, respiratory infection, renal problems, and pain. The HCP may order the administration of IV bisphosphonate agents such as pamidronate (Aredia). This class of drugs inhibits bone resorption and is used to help keep serum calcium levels controlled. Oral compounds are also available to help keep the calcium within normal limits. The goal is to get the serum calcium level below 10 mg/dL.

If hypercalcemia occurs, the HCP will order an IV infusion of normal saline solution at a high rate, follo wed by regular administration of diuretics.

External beam irradiation may be given to especially painful areas of bone in involvement. Fortunately, this treatment is quite effective, usually decreasing pain intensity in just a few days. The patient can expect to have a daily (or perhaps a twice-daily) treatment over a course of 10 to 14 days that is delivered directly to the painful bony areas. Vigorous attention to administering pain medications during the early course of treatment greatly reduces the patient’s pain levels.

The patient may need a laminectomy if vertebral collapse occurs. Because of demineralization of the bone, with resulting large amounts of calcium in the blood and urine, surgery for kidney stones and eventual dialysis for acute or chronic kidney failure may be needed.
Nursing Process for the Patient With Multiple Myeloma

The patient with multiple myeloma is at risk for many problems. In addition to those below, the diagnoses in the “Nursing Care Plan for the Patient With Leukemia” are appropriate.

Data Collection
Assess for fever or malaise, which can signal the onset of infection. Other conditions to be alert for include anemia, hypercalcemia, fractures, and renal complications. Monitor intake and output, and strain urine for stones. Elevated BUN and creatinine levels will alert you to possible renal failure. Report back pain, leg weakness, sensory loss, or loss of bowel or bladder function because these can indicate spinal cord compression. Monitor the patient for elevated CRP and low hemoglobin, which are associated with increased fatigue.

Nursing Diagnoses, Planning, and Implementation

Risk for Infection related to compromised immune function

**EXPECTED OUTCOME:** Patient will remain free from infection as evidenced by temperature within normal limits and no signs or symptoms of infection.

- Intervene as appropriate to reduce the risk of infection (see Box 28-2).
- Encourage deep breathing, and keep patient active to decrease the risk of respiratory complications.

Risk for Injury: Fracture related to weakened bones; complications of immobility; complications due to hypercalcemia

**EXPECTED OUTCOME:** Patient will remain free from injury as evidenced by no fracture and no complications related to immobility or hypercalcemia.

- Keep the patient mobile. Consult physical and occupational therapy as needed. Bones in use are strongest, so the patient should remain up and moving as much as possible to help stimulate calcium resorption and decrease demineralization.
- Assist the patient with walking to reduce the risk of pathological fractures of the long bones.
- If the patient is unsteady, use a walker or a support belt to reduce the risk of falls.
- If the patient is bedridden, reposition every 2 hours to prevent complications related to immobility.
- Use a lift sheet to move the patient gently in bed to decrease the risk of skin damage and pathological fractures.
- Provide passive range-of-motion exercises to maintain mobility if the patient is unable to be independently mobile.
- Administer fluids so that daily output is never less than 1500 mL to flush kidneys and reduce the risk of kidney stones.
- Teach the patient the importance of good hydration at all times to minimize complications of hypercalcemia. Depending on time of year and the type and level of patient activities, the patient may need to have an intake of more than 4 L daily.

Evaluation

If nursing care has been effective, the patient will be free of infection or infection will be recognized and treated promptly. The patient will avoid injury, with no fracture, skin breakdown, or complications related to hypercalcemia. See “Home Health Hints” at the end of this chapter for additional suggestions for patients being cared for at home.

**LYMPHATIC DISORDERS**

Lymphatic disorders include Hodgkin’s disease and the non-Hodgkin’s lymphomas. Because the spleen is part of the lymph system, this section also discusses splenectomy.

Hodgkin’s Disease

Despite its name, Hodgkin’s disease is a lymphoma, which is a cancer of the lymph system. Its distinguishing feature is the presence of Reed-Sternberg cells, which make it different from all the other forms of lymphoma. Hodgkin’s disease is more prevalent in men than in women and occurs most often in young adults ages 15 to 40. After a decrease in incidence in persons aged 40 to 55, the incidence peaks again in adults older than age 55. Of all the lymphomas, Hodgkin’s disease is the most curable type even when the disease is widespread at the time of diagnosis.

Pathophysiology

Lymph nodes are made of tightly bound fibers and cells that serve as filtering devices for the body’s immune system. Most often, Hodgkin’s disease begins as a single changed lymph node, usually in the cervical lymph nodes of the neck. As the disease progresses, the cancer invades the lymph node chains node by node. The path of cancer infiltration is usually the same as the path of lymph fluid flow. Left untreated, other lymphoid tissues such as the spleen become infiltrated with Hodgkin’s disease. The major organs eventually become involved. Common reports of patients with or gan involvement include shortness of breath, feelings of fullness, weakness, and malaise. These organ-related symptoms usually motivate the patient to seek medical help.

A tentative diagnosis of Hodgkin’s disease is based on one or more painlessly enlarged nodes in the cervical, axillary, or inguinal areas. A biopsy of several of the enlarged nodes is performed to search for the presence of Reed-Sternberg cells, which confirms the diagnosis.

Etiology

The exact cause of Hodgkin’s disease is unknown. A possible viral origin has been proposed; it is more common in people who have had mononucleosis. Sometimes it occurs in families, suggesting a genetic link. Patients with...
impaired immune function, such as those with acquired immunodeficiency syndrome (AIDS) or those taking immunosuppressant drugs after organ transplant, are also at higher risk.

**Signs and Symptoms**

Painless swelling in one or more of the common lymph node chains is a usual presentation (Fig. 28.7). Swelling can range from barely perceptible to the size of a softball, occasionally even larger. The patient may report generalized pruritus. One other curious event, alcohol-induced pain, is occasionally present. With just a few sips of any type of alcohol-containing beverage (beer, wine, or liquor), the patient may describe intense pain at the site of disease. Because the lymph nodes in the upper chest and neck are often in volved, the patient may have symptoms of obstruction, such as cough, dysphagia, or stridor.

Other common symptoms include persistent low-grade fever, night sweats, fatigue, weight loss, and malaise. When these additional symptoms are present, the prognosis is worse. In older adults, enlarged lymph nodes might not be visible, so these secondary symptoms may be the only presenting symptoms. Other symptoms associated with late-stage disease include edema of the neck and face, possible jaundice, nerve pain, enlargement of the retroperitoneal nodes, and infiltration of the spleen; liver and bones may also be involved.

**Diagnostic Tests and Staging**

Diagnosis usually begins with a lymph node biopsy of the easiest lymph node to access. Lymph node biopsies are done to check for abnormal histiocyte proliferation, nodular fibrosis, and necrosis. Other tests include bone marrow biopsy and aspiration, liver and spleen biopsies, routine chest x-ray examination, abdominal computed tomography (CT) scan to check for disease in the liver and spleen, lung scan, and bone scan. Lymphangiography may be performed to view the flow of lymph in the lymph network. A gallium scan can also be done to view lymph tissue.

Hematologic tests (e.g., CBC) may show wide variability of RBCs, indicating mild to severe anemia. The WBC count is often abnormal and extreme (either very high or very low) because of bone marrow infiltration by disease. These same tests are used for staging the disease into one of four stages:

- **Stage I disease** is limited to a single lymph node or site or a single organ.
- **Stage II disease** occurs when two or more nodes are involved on the same side of the diaphragm.
- **Stage III disease** affects nodes on both sides of the diaphragm.
- **Stage IV**, the most serious form of the disease and the least curable, includes widely disseminated disease in both lymph nodes and other organs such as bone marrow or liver.

**Therapeutic Measures**

Appropriate therapy includes the use of radiation and chemotherapy and depends on the stage of the disease. Radiation therapy, administered on an outpatient basis over a 4- to 6-week period, can cure most patients with stage I or stage II disease. Combinations of chemotherapy and radiation therapy are used for patients with stage III and stage IV disease. Results vary depending on the location and the stage of disease. If the disease recurs after initial treatment, bone marrow or stem cell transplant may be considered.

**Nursing Management**

Most nursing interventions are aimed at symptom management. If the patient is experiencing pruritus or night sweats, nursing interventions are aimed at alleviation of discomfort. These may include changing the gown and bed linens several times a night and helping the patient remain clean and dry. Keeping the patient and family involved in the plan of care may relieve anxiety.

Later, nursing interventions are tailored to alleviate problems that arise secondary to chemotherapy and radiation therapy. See Chapter 11 for nursing interventions for these
problems. Also see the “Nursing Care Plan for the Patient With Lymphoma.”

**Patient Education**
In addition to the teaching needs outlined above, make sure that the patient and the family know about local chapters of the American Cancer Society and the Leukemia and Lymphoma Society. Both of these organizations provide information, financial assistance, and counseling referral sources, which most patients find valuable. For more information visit the www.lls.org or www.cancer.org.

---

### CRITICAL THINKING

**Jeanie**
- Jeanie is a 60-year-old nurse diagnosed with stage II Hodgkin’s disease. She wishes to continue working at her job on a respiratory unit at the local hospital while she undergoes treatment. What concerns do you have about this?

*Suggested answers are at the end of the chapter.*

---

### NURSING CARE PLAN for the Patient With Lymphoma

**Nursing Diagnosis:** Activity Intolerance related to fatigue and anemia as evidenced by inability to carry out ADLs without excessive fatigue or dyspnea

**Expected Outcome:** The patient will have ADL needs met by self or caregiver as evidenced by patient statement of met needs.

**Evaluation of Outcome:** Is patient able to carry out ADLs or are ADL needs met by a caregiver?

**Intervention** Assess amount of activity that causes fatigue or dyspnea. **Rationale** Assessment helps guide plan of care. **Evaluation** How much can patient do before becoming fatigued or dyspneic?

**Intervention** Assist patient with activities as needed. **Rationale** The patient may need assistance with ADLs if fatigue is extreme. **Evaluation** Does the patient need assistance? Can family members assist?

**Intervention** Provide oxygen therapy as ordered. **Rationale** Oxygen therapy can increase oxygen levels and activity tolerance. **Evaluation** Does patient tolerate activity better with oxygen therapy?

**Intervention** Instruct patient to space rest with activities. **Rationale** Rest periods decrease oxygen needs and allow patient to conserve energy for next activity. **Evaluation** Is patient able to tolerate activity better after a rest period?

---

**Nursing Diagnosis:** Risk for Infection related to bone marrow involvement and side effects of treatment as evidenced by elevated temperature, redness, swelling, or other signs and symptoms based on infection site

**Expected Outcome:** The patient will remain infection free as evidenced by temperature within normal limits and no signs or symptoms of infection.

**Evaluation of Outcome:** Are signs and symptoms of infection absent? Is temperature within normal limits?

**Intervention** Assess patient for risk factors for infection. **Rationale** The WBC count may be very high or very low, placing the patient at risk for infection. **Evaluation** Is the patient at risk? Are additional interventions indicated?

**Intervention** Monitor patient for signs and symptoms of infection, such as cough, fever, malaise, erythema, pain, or drainage and report immediately. **Rationale** Early detection and treatment of infection provide the best results. **Evaluation** Are signs and symptoms of infection present?

**Intervention** Teach patient and significant others signs and symptoms of infection to watch for and report. **Rationale** The patient must be involved in monitoring for infection when at home. **Evaluation** Does patient verbalize understanding of signs and symptoms of infection and importance of reporting?
NURSING CARE PLAN for the Patient With Lymphoma—cont’d

**Intervention** Teach the patient to avoid exposure to others with influenza or other infections. **Rationale** Exposure increases risk for infection, especially with compromised immune function. **Evaluation** Does patient verbalize understanding of sources of infection to avoid?

**Intervention** Teach patient proper hand washing and good oral and personal hygiene. **Rationale** These activities reduce risk of infection. **Evaluation** Does patient demonstrate proper hand washing and hygiene?

**Intervention** Teach hand hygiene and infection risk reduction to family members. **Rationale** Family caregivers can be sources of infection. **Evaluation** Do family members demonstrate appropriate hand hygiene and infection control measures?

**Nursing Diagnosis:** Ineffective Coping related to new diagnosis and potential lifestyle changes to accommodate treatments as evidenced by poor problem solving, lack of goal-directed behavior, statement of poor coping

**Expected Outcome:** The patient will be able to cope effectively as evidenced by statement of ability to manage lifestyle changes and medical management of condition.

**Evaluation of Outcome:** Does patient carry out self-care necessary to manage treatment?

**Intervention** Assess patient’s level of distress related to uncertainty about the future, bothersome symptoms, changes in self-concept, and past coping mechanisms. **Rationale** Obtaining information regarding past experiences helps the nurse identify and correct misconceptions. The nurse can support effective coping mechanisms that worked in the past. **Evaluation** Is patient able to identify sources of anxiety? Are past coping mechanisms effective?

**Intervention** Assess for signs of maladaptive behaviors that interfere with responsible health practices, such as missed appointments or failure to attend to symptoms. **Rationale** Long-term survival depends on keeping the scheduled therapy appointments. The ability to manage and report symptoms early keeps the patient out of the hospital and in control of his or her own life. **Evaluation** Does the patient keep appointments? Does the patient participate in self-care activities and report symptoms promptly?

**Intervention** Assist the patient to identify support systems and resources. Refer to social worker or other community resources as needed. **Rationale** Resources can assist with participation in treatment plan, home care, or financial assistance. **Evaluation** Are resources identified and helpful?

**Intervention** Refer patient and family to a cancer survivors’ support group. **Rationale** Others who have been through treatment can be a good support for patients with cancer. **Evaluation** Does the patient state that the support group is helpful?

Non-Hodgkin’s Lymphomas

All of the other types of lymphomas are clumped into a diverse classification known as the non-Hodgkin’s lymphomas (NHLs). It is possible to sort these other types of lymphomas into different categories based on the degree of malignancy. Non-Hodgkin’s lymphomas arise in the lymphoid tissues of the body, just as Hodgkin’s disease does, but they differ in several ways (Table 28.4).

**Pathophysiology**

The most distinguishing difference is the absence of the Reed-Sternberg cells in NHL. Instead, many of these lymphomas arise from the B cells and T cells. The B cells are involved in recognizing and destroying specific antigens. Cells specifically involved include the memory B cells and the plasma cells. The T cells also are involved in registering antigens, but there are many more kinds of T cells. These include the amplifier T cells, helper T cells, suppressor T cells, memory T cells, cytotoxic T cells, and delayed hypersensitivity T cells. An abnormality in any of these cells can result in a type of NHL. Most cases of NHL are of B-cell origin. Cancerous cells are found most commonly in the lymph nodes, but they can also be found in other lymph tissues such as the tonsils, thymus, or bone marrow.
Etiology

The cause of NHL is unclear, but some viruses, such as the Epstein-Barr and herpes viruses, are thought to play a role in their development. *Helicobacter pylori*, the bacterium that causes ulcers, has been associated with NHL. Genetics plays a role, as do immune problems such as AIDS. People working in farming, printing, medicine, electronics, and leather also have a higher risk for developing NHL.

Signs and Symptoms

Clinical features of malignant lymphomas include enlarged, painless, rubbery nodes in the cervical and supraclavicular areas, axillae, and groin; enlarged tonsils and adenoids; and occasional symptoms of dyspnea and cough. As the disease progresses, the patient may report fatigue, malaise, weight loss, and night sweats similar to Hodgkin’s disease. NHL usually progresses more rapidly than Hodgkin’s disease.

Diagnostic Tests

Diagnosis is confirmed by histological evaluation of biopsied lymph nodes, tonsils, bone marrow, liver, bowel, skin, or other affected tissues. Other relevant tests include bone scans, chest x-rays, lymphangiography, liver and spleen scans, CT of the abdomen, MRI, positron emission tomography (PET) scan, and IV pyelogram to determine the extent of the disease. Laboratory tests include a CBC (which often indicates anemia), serum uric acid level, and liver function studies. Serum calcium level may be elevated if bone lesions are present.

Therapeutic Measures

Treatment usually involves multimodal therapy, including the use of chemotherapy and radiation therapy in combination. Radiation therapy is given to affected areas in advanced stages of NHL. Stem cell transplant may be tried in patients with advanced disease. Newer therapies include the use of monoclonal antibodies to target and destroy cancer cells and interferon therapy to help boost the immune system to fight the cancer.

Nursing Management

You can provide emotional support by keeping the patient and family informed during the testing phase. Symptoms such as night sweats can be managed with frequent linen and gown changes. Help the patient maintain nutrition with attractively prepared meals. Spend time listening to the patient’s concerns; involve the hospital chaplain in the patient’s care if the patient desires. See Table 28.5 and the “Nursing Care Plan for the Patient with Lymphoma” for more information.

Splenic Disorders

The spleen is involved in a number of disorders, including cancers of the blood, lymph, and bone marrow; hereditary conditions such as SCD; and acquired problems such as idiopathic thrombocytopenia. Under normal circumstances, the spleen is not paid much attention; it generally performs its functions without much fanfare.

If the spleen enlarges markedly, the condition is referred to as *splenomegaly*. Other times, the spleen may or may not be enlarged, but the function is out of control so that too many RBCs and platelets are removed from the peripheral circulation. Sometimes the spleen is not able to perform its job because of bleeding into the pulp of the organ, which renders it useless. Bleeding into the spleen can occur from various illnesses or from trauma. Regardless of the nature of the malfunction, one treatment option may be splenectomy.

Splenectomy

*Splenectomy* is the surgical removal of the spleen. This is sometimes used to treat selective hematologic disorders and

monia and respiratory problems. In addition, splenectomy, this splinting behavior may leave the patient at risk for pneumonia, and atelectasis (collapsed alveoli). Respiratory problems occur because of the spleen’s position close to the diaphragm. This placement requires the need for a high surgical incision that is very painful. Often the patient tries to restrict lung expansion after surgery to keep from hurting, but this splinting behavior may leave the patient at risk for pneumonia and respiratory problems. In addition, splenectomy patients are usually more vulnerable to infection, especially influenza, because the spleen’s role in the immune response is no longer filled.

Another possible complication of splenectomy includes the development of pancreatitis. This is because the tail of the pancreas is close to the spleen, and irritation may have occurred.

Another serious complication is overwhelming post-splenectomy infection (OPSI). The causative agents in OPSI include streptococci, Neisseria spp., and influenza bacteria (as opposed to a flu virus). OPSI can occur at any time from 1 week to 20 years after the splenectomy. Patients most at risk are those with poor immune function.

Early symptoms of OPSI include fever and malaise that seem unremarkable. However, the infection may progress within a few hours to sepsis and death. Unfortunately, OPSI has a mortality rate as high as 70%. Be sure to include the signs and symptoms of OPSI in presplenectomy patient education. Also, stress the need to promptly obtain medical attention for the patient at the first signs and symptoms of OPSI. The patient should be directed to continue to receive lifetime vaccinations against these bacteria.

### Patient Education

Explain to patients that this surgery removes the spleen, usually under general anesthesia. Inform patients that the y can live a normal life after the surgery but that they may be more prone to infection and that they should receive the influenza vaccine each year, preferably in the early autumn.

### Preoperative Care

Before the surgery, ensure that the CBC and coagulation profile are completed and reported to the HCP. Blood transfusion may be ordered to correct underlying anemia and to prepare for the loss of a great deal of blood stored in the spleen. Vitamin K is often ordered to correct clotting factor deficiencies.

Check the patient’s vital signs, and perform a baseline respiratory assessment. Note especially any signs of respiratory infections such as fever, chills, crackles, wheezes, or cough. If any of these are noted, make sure that the surgeon is aware of them because surgery may need to be delayed. Teach the patient routine coughing and deep-breathing techniques to help prevent postoperative respiratory complications.

### Postoperative Care

During the early postoperative period, watch carefully for bleeding, either external or internal. Be prepared to administer opioids for pain, usually on an around-the-clock schedule so the patient is comfortable enough to deep breathe, cough, and ambulate. After opioid administration, be sure to observe for side effects, which may include incomplete pain relief or hypoventilation. Monitor for fever every 4 hours, and expect a mild, low-grade, transient fever postoperatively. A persistent fever may indicate abscess or hematoma formation.

If the surgery was performed to decrease the numbers of cells being removed from the peripheral circulation, monitor the platelet count. Often the count be gins to rise in just a few days, but it may take up to 2 weeks for the platelets to normalize.

### Complications

A splenectomy can lead to complications such as bleeding, pneumonia, and atelectasis (collapsed alveoli). Respiratory problems occur because of the spleen’s position close to the diaphragm. This placement requires the need for a high surgical incision that is very painful. Often the patient tries to restrict lung expansion after surgery to keep from hurting, but this splinting behavior may leave the patient at risk for pneumonia and respiratory problems. In addition, splenectomy

**Home Health Hints**

- Patients who are at risk for infection can place a sign on the front door of their homes to limit visitors or ask persons with colds to come back when they are well. The patient may appreciate the home nurse giving permission to be assertive in such circumstances.
- Teach patients with infection risk to avoid working with dirt or soil, to avoid manicures and pedicures, to avoid hot tubs or Jacuzzis, and to wash hands after contact with pets, fresh flowers, or plants.
- To prevent bruising, have the patient cut the feet off of long, white sport socks and wear them on the arms. They can be hidden under long-sleeve shirts and blouses and provide a cushion when doing housework.
- Teach patients with thrombocytopenia to avoid contact sports and to consult with their HCP about whether sexual intercourse is safe.
- Teach patients with thrombocytopenia to avoid over-the-counter medications unless approved by the HCP. Many such agents contain aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs).
- Patients with sickle cell anemia usually have lower blood pressures. It is important to report even mild hypertension in these patients.
- If fatigue or nausea causes poor appetite, discuss eating smaller, more frequent meals. Ask the HCP for an antiemetic order if needed.
CRITICAL THINKING

■ Mrs. Johns

1. Monitor Mrs. Johns’s vital signs and report falling blood pressure and rising pulse immediately. Inspect her skin for petechiae and ecchymoses. Outline ecchymotic areas with a marker to see if the area is increasing in size. Monitor urine for signs of blood. Test stools for occult blood. Monitor vaginal discharge for increasing bleeding. Report any changes promptly.

2. Anticipate assisting the RN with administration of blood or blood products. Instruct Mrs. Johns in the importance of preventing injury that could cause further bleeding. Other care will be supportive.

3. Mrs. Johns will be concerned for her new baby, who is most likely on another unit or already discharged home. Allow Mrs. Johns to talk about her concerns. Arrange visits with her family and baby if permitted by her condition and her HCP.

4.

\[
\frac{300 \text{ mL}}{30 \text{ min}} \times \frac{60 \text{ min}}{1 \text{ hour}} = 600 \text{ mL per hour}
\]

5. Collaborate with the RN, internist, obstetrician, hematologist, neonatal nurse, husband, family, and social worker to provide holistic, patient-centered care for this new mother.

■ Mr. Washington

1. Because of his leukemia and his treatment, Mr. Washington is at risk for infection. If he develops an infection, he will have great difficulty getting over it. With so many visitors in the room, it is likely that one or more has a cold or virus. They may not be aware of the risk this poses to Mr. Washington. Mr. Washington is probably also fatigued because of his disease and treatment, and visiting requires energy.

2. You should kindly explain that although family visits are important, Mr. Washington is very susceptible to catching colds or other illnesses and that it would be best to limit visitors to one or two at a time. Point out that persons with symptoms of colds or flu should not enter the room at all. Visits should also be brief to prevent over-tiring the patient.

Ask Mr. Washington about his preferences, and attempt to honor them if possible. He may choose one or two (healthy!) visitors to come regularly, or choose a time of day when he is less fatigued to have visitors. As his nurse, you can help enforce visiting limitations so Mr. Washington does not have to feel ungracious toward his visitors.

■ Jeanie

Jeanie will probably be fatigued from her disease, and fatigue may increase further as a side effect of treatment. Staff nursing jobs can be tiring even for healthy nurses. In addition, she will be around patients with respiratory diseases, many of whom are contagious. Because of the risk of infection secondary to the disease process and the treatment regimen, Jeanie might want to take a leave of absence during treatment or ask to be reassigned to an area that is less demanding and away from direct patient care until her treatments have been completed.

REVIEW QUESTIONS

1. The nurse is caring for a patient admitted with pancytopenia with complaints of dyspnea upon exertion. This symptom would be most directly related to which condition?
   1. Pain
   2. Thrombocytopenia
   3. Anemia
   4. Neutropenia

2. A nurse is teaching a patient with sickle cell anemia about activities to avoid. Which of the following activities the patient plans to do shows that more teaching is needed?
   1. Going to the beach
   2. Taking a long car trip
   3. Running in a marathon
   4. Listening to a concert

3. The family of a patient with DIC has questions about the bleeding that is occurring. Which statement by the nurse is the best response to explain why the patient is bleeding?
   1. “He is bleeding because he does not have enough RBCs.”
   2. “He is bleeding because his white cells are depleted.”
   3. “He is bleeding because his blood pressure is so high that it forces blood from mucous membranes.”
   4. “He is bleeding because his body’s clotting factors have all been used up.”
Chapter 28  Nursing Care of Patients With Hematologic and Lymphatic Disorders

4. The nurse is teaching the parent of a child with hemophilia. Which of the following statement by the parent demonstrates understanding about preventing bleeding episodes?
1. “My son will have to avoid contact sports.”
2. “My son will have to avoid irritating foods in his diet.”
3. “My son will have to grow a beard.”
4. “My son will always have to live near a major hospital.”

5. Which family member should be restricted from visiting a patient with newly diagnosed leukemia?
1. The one who has a new baby at home
2. The one who has a history of asthma
3. The one who has received recent radiation treatment for cancer
4. The one who has a runny nose

6. Which of the following nursing interventions is a priority for the patient with multiple myeloma found in the ribs and femur?
1. Implement safety measures to prevent falls.
2. Assist with all ADLs.
3. Provide a high-protein, low-sodium diet.
4. Institute neutropenic precautions.

7. Which of the following nursing interventions are appropriate for a patient with thrombocytopenia? Select all that apply.
1. Avoid intramuscular injections.
2. Keep visitors who are ill away from the patient.
3. Encourage 4 L of fluid daily.
4. Avoid use of aspirin and NSAIDs.
5. Allow rest between activities.
6. Encourage use of shoes or slippers.

8. A patient with hypercalcemia needs to drink at least 3 L of fluid per day. Today, he has had 1 measuring cup of coffee, 1 L of water, a can of soda that says it has 355 mL, and a half cup of juice. How many milliliters has he had so far today? Fill in the blank. Answer: __________ mL

9. What assessment data will best help the nurse determine if interventions for neutropenia have been effective?
1. Temperature
2. Fatigue level
3. Oxygen saturation
4. Hemoglobin level

10. Which circumstance places the patient at most risk for postoperative pneumonia following a splenectomy?
1. Disturbance of clotting factors
2. Nothing by mouth (NPO) status
3. Need for frequent dressing changes
4. Location of surgical incision

Answers can be found in Appendix C.

LEARNING OUTCOMES

1. Describe the normal structures and functions of the respiratory system.
2. Identify how aging affects the respiratory system.
3. List data to collect when caring for a patient with a respiratory disorder.
4. Recognize expected findings when inspecting, palpating, percussing, and auscultating the chest.
5. Identify common diagnostic tests performed to diagnose disorders of the respiratory system.
6. Plan nursing care for patients undergoing each of the diagnostic tests.
7. Discuss therapeutic measures used to help patients with respiratory disorders.
NORMAL RESPIRATORY SYSTEM
ANATOMY AND PHYSIOLOGY

The respiratory system is basically a tract, divided into upper and lower respiratory portions. The upper tract is above the thoracic cavity, and the lower portion is within the thoracic cavity. The alveoli of the lungs are the site of gas exchange between the air and the blood of pulmonary circulation; the rest of the system moves air into and out of the lungs. Together with the cardiovascular system, the respiratory system supplies the body with oxygen and eliminates carbon dioxide.

Nose and Nasal Cavities

The nose is made mostly of bone and cartilage covered with muscle and epithelium. Hairs inside the nostrils block the entry of dust and other particles. The nasal cavities are separated at midline by the nasal septum, which is made of bone and cartilage. The nasal mucosa is highly vascular, ciliated epithelium that warms and moistens inhaled air. Dust and microorganisms become trapped on mucus produced by goblet cells and are swept back into the pharynx by the cilia. See Table 29.1 for a summary of protective mechanisms in the respiratory system. The paranasal sinuses are air cavities in the maxillary, frontal, sphenoid, and ethmoid bones that open into the nasal cavities, releasing mucus. The sinuses lessen the weight of the skull and provide resonance for the voice.

Pharynx

The pharynx is posterior to the nasal and oral cavities. It has three regions (Figure 29.1). The soft palate and uvula rise to block the nasopharynx during swallowing. The lingual tonsils, the adenoid (pharyngeal tonsil), and the palatine tonsils form a ring of lymphatic tissue around the pharynx and destroy pathogens that penetrate the mucosa.

Larynx

The larynx is the airway between the pharynx and trachea. It houses the vocal cords and produces sound that can be formed into speech. The epiglottis at the top of the larynx prevents ingested materials from entering the trachea (Figure 29.2). The cartilaginous walls are lined with ciliated epithelium. The vagus and accessory cranial nerves innervate the larynx.

Trachea and Bronchial Tree

The trachea descends from the larynx to the primary bronchi (Figure 29.3). The mucosa is ciliated epithelium; mucus with trapped dust and microorganisms is swept upward toward the pharynx and is swallowed. Deeper into the bronchial tree, cartilage diminishes, and smooth muscle in the walls increases. The bronchioles have no cartilage in the walls to maintain patency, therefore they can be closed completely by bronchoconstriction.

Lungs and Pleural Membranes

The lungs occupy the thoracic cavity on each side of the heart, extending from the clavicles to the diaphragm, and are protected by the ribs (costae). On the medial (mediastinal) surface of each lung is an indentation called the hilus, where the primary bronchus and the pulmonary vessels enter the lung (Figure 29.4). A thin layer of fluid between the visceral and parietal pleural membranes provides lubrication to reduce friction during lung expansion.

The functional units of the lungs are the millions of alveoli, the air sacs where gas exchange occurs. Both the alveoli and the surrounding alveolar capillaries are made of simple squamous epithelium; that is, their walls are only one cell in thickness to permit diffusion of gases (see Fig. 29.5). Each alveolus is lined with a thin layer of tissue fluid that is essential for the diffusion of gases, but the surface tension of the fluid tends to make the walls of an alveolus stick together internally. Alveolar cells secrete surfactant, a lipoprotein that mixes with the tissue fluid and decreases surface tension to permit inflation.

Between clusters of alveoli is elastic connective tissue that can stretch during inhalation and recoil during exhalation. The recoil of this tissue allows passive exhalation without the expenditure of energy.

**Mechanism of Breathing**

*Ventilation* is the term for the movement of air into and out of the alveoli. The primary respiratory muscles are the diaphragm, inferior to the lungs, and the external intercostal muscles, between the ribs. Accessory muscles of respiration are used during exercise and times of respiratory distress. These include muscles for deep inspiration (sternocleidomastoid, scalene, pectoralis minor) and for forced expiration (internal intercostal muscles and abdominal musculature; Figure 29.6). Respiratory centers of the brain, located in the medulla oblongata and pons, innervate muscles of respiration via the intercostal and phrenic nerves. A normal respiratory rate is 12 to 20 breaths/minute.

Ventilation is accomplished by respiratory muscle contractions, causing changes in lung volumes. Movement of air follows Boyle’s Law, which states that in a closed container of gases, volume and pressure are inversely related. Air moves from high-pressure to low-pressure areas.

---

**Figure 29.2 Larynx.** From Thompson, G. S. (2013). *Understanding anatomy and physiology.* Philadelphia: F.A. Davis, p. 329.
Inhalation

Inhalation, also called inspiration, occurs when motor impulses from the medulla cause contraction of the respiratory muscles. Impulses travel along the phrenic nerves and cause the dome-shaped diaphragm to contract and flatten inferiorty. Intercostal nerves cause the external intercostal muscles to expand the thoracic cavity in the anteroposterior dimension. These movements then expand the pleural membranes and therefore the lungs due to adhesion from serous fluid. As the lungs expand, alveolar pressure falls below atmospheric pressure, and air enters the nose and respiratory passages. A deeper inhalation requires a more forceful contraction of the respiratory muscles (including accessory inspiratory muscles) to expand the thoracic cavity and lungs even further. Ease of thoracic and lung expansion is called compliance.
Exhalation

Normal exhalation is a passive process. The lungs are compressed as the thoracic cavity reduces volume and the recoil of the elastic lung tissue compresses the alveoli. Alveolar pressure rises above atmospheric pressure, and air is forced out of the lungs. At rest, energy is not used in exhalation because no muscle contraction is required. Forced exhalation is an active process, requiring contraction of the internal intercostal muscles compressing the thorax, and abdominal muscles that force the diaphragm superiorly, increasing compression of the lungs.

Transport of Gases in the Blood

Ninety-eight-and-a-half percent of oxygen is carried in the blood, bound to iron of hemoglobin (Hgb) in red blood cells (RBCs). Oxyhemoglobin is formed in the lungs, where the partial pressure of oxygen (PO\textsubscript{2}) is high. In tissues where the PO\textsubscript{2} is low, hemoglobin releases much of its oxygen. The remaining oxygen is dissolved in the plasma.

Most carbon dioxide (70%) is carried as bicarbonate ion in the blood plasma. These ions form when carbon dioxide enters RBCs and is converted to carbonic acid (H\textsubscript{2}CO\textsubscript{3}), which ionizes into bicarbonate ions (HCO\textsubscript{3}{^-}) and hydrogen ions (H\textsuperscript{+}). The bicarbonate ions leave the RBCs for the plasma, and the remaining hydrogen ions are buffered by the hemoglobin in the RBCs. When the blood reaches the lungs, an area of lower partial pressure of carbon dioxide (PCO\textsubscript{2}), these reactions are reversed—carbon dioxide is reformed and diffuses into the alveoli to be exhaled. Carbon dioxide is also transported as carbaminohemoglobin (23%) and dissolved in plasma (7%).

Chemical Regulation and Respiration

Chemoreceptors (in the carotid and aortic bodies), monitor blood levels of oxygen, carbon dioxide, and pH. The medulla responds by increasing respiration during hypoxemia, hypercapnia, and/or acidemia.

Respiration and Acid–Base Balance

Because of its role in regulating the amount of carbon dioxide in body fluids, the respiratory system is important in the maintenance of acid–base balance, measured by blood pH. Any decrease in the rate or efficiency of respiration permits excess carbon dioxide to accumulate in the blood. The
resulting accumulation of excess hydrogen ions lowers pH. This is called respiratory acidosis and can occur as a consequence of pulmonary disease or an impairment of gas exchange in the lungs.

Respiratory alkalosis occurs when the rate of respiration increases, eliminating exhaled carbon dioxide rapidly. Less carbon dioxide in the blood means fewer hydrogen ions are formed and the pH rises. Although it is not a common condition, respiratory alkalosis may occur during states of anxiety and hyperventilation, or when acclimating to a high altitude, before RBC production increases to provide sufficient oxygenation of tissues.

The respiratory system also helps compensate for pH changes that are metabolic—that is, due to any cause other than respiratory. Metabolic acidosis occurs when the concentration of hydrogen ions in body fluids is above normal due to lowered HCO₃⁻ buffer. Common causes include kidney disease, uncontrolled diabetes mellitus, and severe diarrhea. Respiratory compensation involves an increase in the rate and depth of respiration to exhale more carbon dioxide, which decreases hydrogen ion formation and raises the pH toward normal. Metabolic alkalosis can be caused by overingestion of antacid medications or by vomiting acidic gastric contents. Respiratory compensation involves a decrease in the breathing rate to retain carbon dioxide in the body, increasing the formation of hydrogen ions, which lowers the pH toward normal.

Respiratory compensation for an ongoing metabolic pH imbalance (such as kidney failure) cannot be complete because the amount of carbon dioxide that may be exhaled or retained is limited. At most, respiratory compensation is only about 75% effective.

Acid–base balance is discussed further in Chapter 6.

**Effects of Aging on the Respiratory System**

See Figure 29.7 for the effects of aging on respiration.
Inspiration

- The **external intercostal** muscles pull the ribs upward and outward, widening the thoracic cavity.
- The **internal intercostals** help elevate the ribs.
- The **diaphragm** contracts, flattens, and drops, pressing the abdominal organs downward and enlarging the thoracic cavity.
- Air rushes in to equalize pressure.

Expiration

- The **internal intercostal** muscles pull the ribs downward as the external intercostals relax.
- The **diaphragm** relaxes, bulging upward and pressing against the base of the lungs, reducing the size of the thoracic cavity.
- Air is pushed out of the lungs.

**FIGURE 29.7** Effects of aging on respiration.
NURSING ASSESSMENT OF THE RESPIRATORY SYSTEM

Health History

Many factors in a patient’s personal and family history affect respiratory function. Questions to ask while assessing the patient with a history of respiratory dysfunction are presented in Table 29.2. If at any time while you are taking the history the patient relates a specific symptom, redirect the line of questioning to further assess that symptom. One such line of questioning, as presented in Chapter 1, is the WHAT’S UP? format. For example, if the patient reports shortness of breath, respond with the following questions:

- Where is it? (Doesn’t apply to shortness of breath, so it may be skipped.)
- How does it feel? Does your breathing feel tight, gasping, painful, suffocating?
- Aggravating and alleviating factors? How much activity causes your shortness of breath? Does anything else aggravate it? What do you do to lessen your shortness of breath?

### TABLE 29.2 SUBJECTIVE DATA COLLECTION FOR THE RESPIRATORY SYSTEM

<table>

<tbody>
<tr>
<td>Upper Respiratory Tract</td>
<td>Do you often have headaches or sinus tenderness?</td>
<td>These may indicate sinusitis.</td>
</tr>
<tr>
<td></td>
<td>Do you often experience nosebleeds?</td>
<td>A history of nosebleeds may indicate an abnormality that can predispose to future nosebleeds.</td>
</tr>
<tr>
<td></td>
<td>Has your voice changed?</td>
<td>A voice change may indicate a variety of disorders of the nose or throat, including cancer.</td>
</tr>
<tr>
<td>Lower Respiratory Tract</td>
<td>Do you ever feel short of breath, like you can’t get enough air?</td>
<td>Many respiratory and cardiac problems result in shortness of breath.</td>
</tr>
<tr>
<td></td>
<td>Do you have a cough? Is it productive?</td>
<td>A cough indicates respiratory irritation or excessive secretions.</td>
</tr>
<tr>
<td></td>
<td>What does the sputum look like?</td>
<td>Yellow, tan, or green sputum may accompany an infection. Blood in the sputum is usually serious; it can occur with pneumonia, tuberculosis, pulmonary embolism, or cancer.</td>
</tr>
<tr>
<td></td>
<td>Have you recently experienced night sweats, chills, or fever?</td>
<td>These are symptoms of tuberculosis. These symptoms might indicate a low PO$_2$, reducing oxygen to the brain. This may reveal problem areas the patient has not yet mentioned.</td>
</tr>
<tr>
<td></td>
<td>Do you ever feel confused, light-headed, or restless?</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Have you had any chest surgeries?</td>
<td></td>
</tr>
<tr>
<td>Exposures</td>
<td>Do you have any allergies that cause respiratory symptoms? How do you treat them?</td>
<td>The patient may take over-the-counter medications for allergies that affect respiratory function or interact with prescribed medications.</td>
</tr>
<tr>
<td></td>
<td>Do you smoke?</td>
<td>Many respiratory disorders are caused or aggravated by exposure to tobacco smoke.</td>
</tr>
<tr>
<td></td>
<td>How many packs per day?</td>
<td>Pollutants such as asbestos, radon, coal dust, or chemicals can cause lung disease.</td>
</tr>
<tr>
<td></td>
<td>For how many years?</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Are you exposed to environmental smoke?</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Have you been exposed to airborne pollutants at home or work?</td>
<td></td>
</tr>
<tr>
<td>Treatments</td>
<td>Do you take any medications or use inhalers (prescribed or over-the-counter) for your respiratory problems?</td>
<td>Information about medications gives further information about disorders, severity, and treatment. You should also consider drug interactions and side effects.</td>
</tr>
<tr>
<td></td>
<td>Do you use home oxygen or other home respiratory treatments?</td>
<td>This helps determine the severity of disease and the treatment.</td>
</tr>
<tr>
<td>Family History</td>

</table>
• Timing? When did you first experience shortness of breath? Does it happen more at any particular time of day or year?
• Severity? Rate your shortness of breath on a scale of 0 to 10, with 0 being easy breathing and 10 being the worst shortness of breath you can imagine.
• Useful other data? Do you have any other symptoms that occur along with the shortness of breath?
• Patient’s perception? What do you think is causing your shortness of breath?

Because smoking is such a major risk factor for many types of lung disease, it is essential to ask about smoking history and encourage the patient to quit (see the discussion of smoking cessation later in this chapter). Document the patient’s smoking history in terms of pack-years. For example, if a patient has smoked two packs of cigarettes per day for 20 years, he has a 40 pack-year smoking history ($2 \times 20 = 40$ pack-years). It is also important to be aware of cultural influences on the patient’s respiratory health (see “Cultural Considerations”).

**Physical Examination**

**Inspection**

Inspection begins during the nursing history and continues during the physical assessment. Start with the nose, observing for symmetry, swelling, or other abnormalities. Note whether the patient is short of breath while speaking or moving. If the patient feels very breathless, he or she may speak in short sentences.

Observe the patient for use of accessory muscles of breathing (Fig. 29.8). Use of the sternocleidomastoid muscles causes the shoulders to rise during labored inspiration. During forced expiration, the abdominal and intercostal muscles contract. The use of accessory muscles for breathing indicates respiratory distress. **Retraction** of the chest wall between the ribs occurs when airways are obstructed and can indicate serious distress. When the patient inhales and air can’t easily flow into the lungs, negative pressure in the chest pulls the soft tissue between the ribs inward.

Note the color of the skin, lips, mucous membranes, and nailbeds. A bluish color is called **cyanosis** and is a late sign of oxygen deprivation. Observe the trachea and chest for symmetry. Count the number of respirations per minute, noting depth and rhythm. Irregular respirations, or periods of **apnea** (absence of respirations), can indicate a pathological condition and are described in Figure 29.9. Observe the

---

**Cultural Considerations**

Pulmonary diseases associated with Japanese people include asthma related to dust mites in the straw mats that cover floors in Japanese homes and air pollution from living in urban areas. Encourage patients who have straw mats and who wish to keep them to have them sterilized.

Patients from Poland, Ireland, or other countries where mining is a primary occupation may have an increased incidence of respiratory disease. It is essential for health care providers (HCPs) to carefully screen Polish and Irish immigrants for respiratory conditions.

HCPs also should be aware of variations among ethnic peoples of color when assessing for cyanosis. Cyanosis and decreased blood hemoglobin levels in darker-skinned individuals give the skin an ashen color instead of the bluish color seen in light-skinned people. Thus, the nurse must examine the sclerae, conjunctivae, buccal mucosa, tongue, lips, nailbeds, and palms and soles of the feet to assess for cyanosis.

Smoking is deeply ingrained in the Arab-American culture. Offering cigarettes is a rite of Arab hospitality. Arab individuals may have difficulty stopping smoking because of these cultural rituals.

Strategies to increase the effectiveness of smoking cessation in African Americans include working with community and church groups in African American communities. Populations living in inner cities are at increased risk for respiratory diseases related to pollution.
Respiratory patterns

When assessing a patient’s respirations, the nurse should determine their rate, rhythm, and depth. These schematic diagrams show different respiratory patterns.

- **Eupnea:** Normal respiratory rate and rhythm
- **Tachypnea:** Increased respiratory rate
- **Bradypnea:** Slow but regular respirations
- **Apnea:** Absence of breathing (may be periodic)
- **Hyperventilation:** Deeper respirations; normal rate
- **Cheyne-Stokes:** Respirations that gradually become faster and deeper than normal, then slower; alternates with periods of apnea
- **Kussmaul’s:** Faster and deeper respirations without pauses

**FIGURE 29.9 Abnormal respiratory patterns.**

rest at intervals to prevent hyperventilation. Regular and frequent practice helps you learn to distinguish normal from abnormal breath sounds. Abnormal extra sounds (another term is adventitious) indicate a pathological condition and are described in Table 29.4.

**Learning Tip**

Listen to breath sounds on all your friends and family members. Assuming they are normal, this will give you a good baseline so when you hear an abnormal or adventitious sound on a patient, you will recognize it as “not normal.”

**Critical Thinking**

Timothy

- Timothy is a 16-year-old whose mother brought him to the emergency room because of an asthma attack. He says he feels short of breath, but when you listen to his lungs, you hear no wheezing.

1. Does Timothy really need to be in the emergency room?
2. What should you do?
3. What do you think could be happening?
4. What other team members can you collaborate with as you care for Timothy?

Suggested answers are at the end of the chapter.

**Diagnostic Tests for the Respiratory System**

**Laboratory Tests**

For normal values for the following laboratory tests, see Appendix B.

**Blood Tests**

**Complete Blood Count.** Measurement of RBCs and hemoglobin can give information about the oxygen-carrying capacity of the blood. **Dyspnea** (shortness of breath) can be caused by a reduction in RBCs or hemoglobin. Elevated white blood cells (WBCs) indicate infection. See Table 29.5 for normal blood count values.

ARterial Blood Gas Analysis. Arterial blood gases (ABGs) are measured to determine the effectiveness of gas exchange. See Table 29.6 for a basic interpretation of ABGs. The blood sample is usually taken from the radial artery in the wrist by a respiratory therapist (RT) or laboratory technician specially trained to do this. This can be painful for the patient. Place pressure on the site for 5 minutes after the test to prevent bleeding.

**LEARNING TIP**

If you remember that a normal blood pH is 7.35 to 7.45, then it is easy to remember that a normal PaCO2 is 35 to 45 mm Hg.

**LEARNING TIP**

Remember 50! If the PaO2 falls below 50 and the PaCO2 is above 50, the patient is in trouble and the health care provider should be notified. This is a crude analysis, but it is helpful when a quick assessment is needed.

_D-DImer._ This blood test measures fibrin degradation products, which are present if there is a blood clot in the body. It helps diagnose the presence of a pulmonary embolism.

**Sputum Culture and Sensitivity**

A sputum culture identifies pathogens present in the sputum. The sensitivity test determines which antibiotics will be effective against those pathogens. To obtain a sputum specimen, first obtain a sterile container. Some institutions have special containers for sputum that help prevent transmission of infection to the HCP (Fig. 29.13). Instruct the patient to take several deep breaths and then cough sputum into the container. It is important that the patient not simply spit saliva or sinus drainage into the cup. The specimen must come from the lungs. It may be easiest to obtain a specimen first thing in the morning (after mouth care) because secretions build up during the night. Send the specimen to the laboratory immediately. If the patient is unable to cough up sputum, extra fluids or a bedside humidifier may help. An RT may be able to help obtain a specimen with a nebulized mist treatment or with a special suction catheter with a sputum trap. A HCP’s order may be needed for these procedures.

**Throat Culture**

A throat culture is done to determine the presence of viral or bacterial pathogens in the pharynx. Use a swab to reach into the posterior pharynx behind the uvula (without touching the patient’s mouth) and swab the red area or lesions. Use a tongue blade to help hold the tongue down while...
obtaining the culture. Warn the patient that a gag reflex may be triggered. Once the culture has been obtained, place it in a sterile tube with culture medium, according to package instructions. Send it to the laboratory immediately for analysis.

**Nasal Samples**

A nasopharyngeal swab or a nasal wash can be used to identify flu or other respiratory viruses. To be accurate, it must be done in the first few days a person has symptoms. The sample may be obtained by swabbing the nasal passages or pharynx or by using a small amount of saline to wash out the nose, depending on the type of test ordered.

**Oxygen Saturation**

The oxygen saturation test (also called pulse oximetry O2 sat, or Spo2) is a simple and noninvasive way to measure arterial oxygenation. A sensor is placed on the patient’s finger or ear. The sensor measures the percentage of hemoglobin that is saturated with oxygen. Oxygen saturation can be measured at rest or while the patient is walking to determine the patient’s exercise tolerance. It is also often done with and without supplemental oxygen to determine the patient’s need for oxygen supplementation at home. See Table 29.6 for normal values. Collaborate with the HCP for an appropriate Spo2 level for your patient. Although 95% or greater is considered normal, some patients with chronic lung disease may be maintained at 90% to 92%. If the Spo2 is less than 75%, prepare for emergency intervention.

Oxygen saturations may be inaccurate in patients with low blood flow or decreased perfusion, patients who are moving, and patients who have smoke inhalation injury or carbon monoxide poisoning. Dark-skinned patients may have falsely high readings. Acrylic nails may need to be removed for accurate readings. Always correlate Spo2 results with patient assessment findings.

**Capnography**

The process of measuring a person’s exhaled carbon dioxide level is called capnography. It provides a continuous measurement of the patient’s ventilation status. In the past, capnography was done primarily during surgery by an anesthetist. Now it is becoming more common in emergency departments and intensive care units; even emergency medical technicians are using it. It is most often used when patients are intubated. A special sensor is placed between the endotracheal tube and the ventilator to measure the exhaled carbon dioxide. Special nasal cannulas with sensors are also now available. Results are displayed on a special monitor.

**Other Tests**

For explanations of the following diagnostic tests, see Appendix A.

---

**Chest X-Ray Examination**

A chest x-ray examination may be ordered to help diagnose a variety of pulmonary disorders. Usually, posterior–anterior (PA) and side views (lateral) are taken. If a hospitalized patient is too ill to go to the radiology department, a portable chest x-ray machine can be used at the bedside to obtain a PA view.

**Computed Tomography**

A computed tomography (CT) scan can show cancers, pneumonia, emphysema, and more. It may be used to obtain more information after an abnormal chest x-ray. A spiral CT scan can be useful for evaluating trauma or blood vessel abnormalities in the chest.

**Ventilation-Perfusion Scan**

During a ventilation-perfusion scan (also called a lung scan or VQ scan), a radioactive substance is injected intravenously, and a scan is done to view blood flow to the lungs (perfusion). Another radioactive substance is inhaled, and scanning shows how well oxygen is distributed in the lungs (ventilation). If an area of the lungs is well ventilated but has no blood supply, a pulmonary embolism is suspected. Chronic lung disease may cause poor ventilation and perfusion.

**Pulmonary Function Studies**

Pulmonary function studies are a series of tests done to determine lung volume, capacity, and flow rates. These are commonly used to help diagnose and monitor restrictive or obstructive lung disease. The patient is asked to use a special mouthpiece to blow into a cylinder that is connected to a computer. A computer printout is generated to show the results. See Table 29.7 for normal values. Some patients use handheld peak expiratory flow rate (PEFR) meters at home to monitor asthma symptoms. They might notice changes in PEFR before symptoms occur, allowing them to begin treatment before the problem becomes more serious.

**Pulmonary Angiography**

Pulmonary angiography involves an x-ray examination of the pulmonary vessels after intravenous (IV) administration of a radiopaque dye. Pulmonary angiography is used to help diagnose pulmonary embolism or other pulmonary vessel disorders.

**Bronchoscopy**

Bronchoscopy involves the use of a flexible endoscope to examine the larynx, trachea, and bronchial tree. Bronchoscopy can be used diagnostically for visualization or to obtain a biopsy specimen for examination. It can also be used therapeutically to remove an obstruction, foreign body, or thick secretions.
respiratory disorders are caused or aggravated by smoking, and stopping can prevent disease from occurring or slow its progression significantly. Table 29.8 lists interventions to help patients stop smoking. Remind patients that if they have tried quitting before and failed, that does not mean that they will never be able to quit (see “Evidence-Based Practice”). Many patients try several times before quitting.

Therapeutic Measures for the Respiratory System

#### Smoking Cessation

Probably the most important intervention for preventing and treating respiratory disease is smoking cessation. Many
Instead of closing the glottis to generate a forceful cough, instruct the patient to deep breath and cough, as above. This lapse easily.

Patients with chronic obstructive pulmonary disease (COPD) typically have a weak cough and airways that collapse easily. Huff coughing may work better for them. Instruct the patient to deep breath and cough, as above. Instead of closing the glottis to generate a forceful cough, the patient should keep the glottis and mouth open, and use the abdominal muscles to create a series of forced expirations, moving air and mucus up the bronchial tree. This creates “huff” or “who” sounds. A short “huff” helps clear larger airways, and a longer “huff” held out for several seconds helps open and clear smaller airways. Finally, the patient should take one more controlled inhalation and a final huff cough to expel the mucus.

**Autogenic Drainage**

Autogenic drainage is a variation on deep breathing and coughing that may be more effective for patients with thick secretions that are difficult to raise, such as those with cystic fibrosis or severe COPD. It is also gentler and less likely to cause declines in oxygen saturation or uncontrolled coughing than other methods. The patient is taught to sit upright and breathe in more deeply than usual, slowly through the nose, and then hold the breath for 2 to 4 seconds. When holding the breath, the patient should keep the glottis open, to prevent airway collapse. Exhaling is done as a quiet sigh, as if trying to steam up a mirror.

Using these breathing techniques, the patient is taught three phases:

1. **Unstick.** The patient breathes out completely and then takes a slow breath and exhales fully several times, suppressing the urge to cough. This loosens mucus in the lower airways.
2. **Collect.** The patient takes 10 to 20 slightly deeper breaths, exhaling normally, still suppressing the urge to cough. This helps move mucus up to the middle airways.
3. **Evacuate.** The patient takes 10 to 20 breaths and huff coughs to move the mucus up and out.

During the unstick and collect phases, airflow should be high enough to produce a rattle if secretions are present. This is a complex process that is typically taught by an RT.

**Breathing Exercises**

Breathing exercises are essential for patients with chronic lung disease. Diaphragmatic and pursed-lip breathing increase the effectiveness of breathing and help reduce panic when dyspnea occurs.

**Diaphragmatic Breathing**

The diaphragm is the major muscle of breathing, but patients often use less efficient accessory muscles when they are short of breath. Conscious use of the diaphragm during breathing can be relaxing and conserve energy. With practice, the patient should be able to use diaphragmatic breathing all the time without thinking about it. Teach the patient to do the following:

1. Place one hand on the abdomen and the other on the chest.
2. Concentrate on pushing out the abdomen during inspiration and relaxing the abdomen on expiration. The chest should move very little.

Many Internet sites have information to help people stop smoking. Among these are the American Lung Association site at www.lungusa.org and the National Lung Health Education Program at www.nlhep.org. Or simply type “smoking cessation” into any search engine. The American Lung Association has a “Freedom From Smoking” online smoking cessation program that can be accessed at www.ffsonline.org. Alternatively, individuals can call 1-800-QUIT NOW to speak with a representative who will assist with cessation strategies.
**Pursed-Lip Breathing**

This technique can be used any time the patient feels short of breath. It helps keep airways open during exhalation, which promotes carbon dioxide excretion. It should be done with diaphragmatic breathing. Counting during breathing also distracts the patient, reducing panic. Teach the patient to do the following:

1. Inhale slowly through the nose to the count of two (using diaphragmatic breathing).
2. Exhale slowly through pursed lips to the count of four.

**NURSING CARE TIP**

When teaching a patient to do pursed-lip breathing, try teaching them to “smell the roses” while inhaling slowly through the nose, and “blow out the candle” while exhaling. If you remind them not to let the wax splatter, then they’ll blow slowly and gently!

**Positioning**

The patient who is short of breath should be positioned to conserve energy while allowing for maximum lung expansion. Most respiratory patients do not tolerate lying flat. The patient in bed can use Fowler’s or semi-Fowler’s position to keep abdominal contents from crowding the lungs. Some patients prefer to sit in a chair while leaning forward and placing their elbows on their knees or an overbed table (tripod position, Fig. 29.14).

**Oxygen Therapy**

Oxygen therapy is ordered by the HCP when the patient is unable to maintain oxygenation. Patients are typically placed on supplemental oxygen when their oxygen saturation is less than 90% on room air. The HCP’s order should include the method of administration and the flow rate. A variety of delivery methods are described in the following sections. The role of the nurse in oxygen therapy includes monitoring the flow rate, ensuring that the cannula and tubing or other device remain properly placed, and monitoring the patient’s response to treatment. If the patient becomes short of breath while on oxygen therapy, an RT, registered nurse (RN), or HCP should be notified. Instruct the patient to avoid smoking, using electrical equipment, and performing other activities that can cause fire in the presence of oxygen. The RT is knowledgeable about oxygen therapy and is an excellent resource when questions arise.

**NURSING CARE TIP**

If a patient suddenly becomes confused, check the SpO2 and oxygen delivery system. The patient may have taken off the cannula, or the tubing may be kinked or disconnected, resulting in hypoxia and confusion.

**Low-Flow Devices**

**NASAL CANNULA.** The nasal cannula is the most common method of oxygen administration. Oxygen is delivered through a flexible catheter that has two short nasal prongs (Fig. 29.15). For the nasal cannula to be most effective, the patient must breathe through his or her nose. The cannula allows the patient to eat and talk, and it is generally more comfortable than other methods of administration. If the nasal mucous membranes become dry, a water source can be placed on the system to humidify the oxygen. Oxygen can...
be delivered at 1 to 6 L/min via a nasal cannula; special high-flow cannulas can deliver much higher rates.

Masks. Masks are used when a higher oxygen concentration is needed (Fig. 29.16). A disadvantage of masks is that they make some patients feel claustrophobic. Also, a mask must be replaced by a cannula while the patient eats.

- **Simple face mask.** A rate of 5 to 10 L/min can deliver oxygen concentrations from 40% to 60% with a simple face mask.
- **Partial rebreather mask.** A partial rebreather mask uses a reservoir to capture some exhaled gas for rebreathing. Vents on the sides of the mask allow room air to mix with oxygen. It can deliver oxygen concentrations of 50% or greater.
- **Nonrebreather mask.** A nonrebreather mask has one or both side vents closed to limit the mixing of room air with oxygen. The vents open to allow exhalation but remain closed on inhalation. The reservoir bag has a valve to store oxygen for inhalation but does not allow entry of exhaled air. It is used to deliver oxygen concentrations of 70% to 100%.

**NURSING CARE TIP**

When a patient is using a partial rebreather or nonrebreather mask, ensure that the reservoir bag is never allowed to collapse to less than half full.

**High-Flow Devices**

**VENTURI MASK.** A Venturi mask is used for the patient who requires precise percentages of oxygen, such as the patient with chronic lung disease with CO₂ retention. A combination of valves and specified flow rates determines oxygen concentration.

**Transtracheal Catheter**

A transtracheal catheter is a small tube that is surgically placed through the base of the neck directly into the trachea to deliver oxygen (Fig. 29.17). This is an attractive alternative for some patients who are on long-term oxygen therapy at home because it does not obstruct the nose or mouth and can be easily covered with a loose scarf or collar. The patient is taught to remove and clean the catheter two or three times a day to prevent mucus obstruction. Check institution policy and procedure for specific care instructions.

**Risks of Oxygen Therapy**

Patients with COPD usually have chronically high PaCO₂ levels. Therefore, they depend on low PaO₂ levels to stimulate breathing, and high supplemental oxygen flow rates can depress respirations. Patients with COPD who retain CO₂ should be maintained on no more than 1 to 2 L of oxygen per minute. Occasionally, hospitalized patients require higher flow rates, but they must be carefully monitored and may require mechanical ventilation.
In addition, any patient can suffer lung damage from high oxygen concentrations delivered for more than 24 hours. If a patient exhibits symptoms of dry cough, chest pain, numbness in the extremities, lethargy, or nausea, the HCP should be contacted. A PaO₂ greater than 100 mm Hg should also be reported.

**Nebulized Mist Treatments**

Nebulized mist treatments (NMTs) use a nebulizer to deliver medication directly into the lungs (Fig. 29.18). Such topical use of medication reduces systemic side effects. Bronchodilators such as albuterol, mixed with normal saline solution and sometimes with supplemental oxygen, are most commonly administered. Other medications, including corticosteroids, mucolytics, and antibiotics, may also be given. An RT or a specially trained nurse administers the NMT. The patient uses a handheld reservoir with tubing and a mouthpiece to breathe in the medication. NMTs are commonly ordered every 4 to 6 hours and as needed. You may call for an NMT as needed (prn) when a patient with chronic pulmonary disease becomes acutely dyspneic. Some patients are taught to administer their own NMTs at home.

**Metered-Dose Inhalers**

Inhalers are another way to administer topical medication directly into the lungs, minimizing systemic side effects. Medications that can be inhaled include corticosteroids, bronchodilators, and mast cell inhibitors. Metered-dose inhalers (MDIs) use propellants to deliver medication. Figure 29.19 shows use of a metered-dose inhaler.

1. Gently twist the canister into the inhaler unit. Shake the inhaler and remove the cap.
2. Exhale.
3. Place the inhaler mouthpiece in your mouth.
4. Press the canister down to actuate a dose of medication. As you do so, breathe in slowly and deeply. Time the dose and breath so the medication goes into the lungs and not onto the tongue.
5. Hold your breath for 5 – 10 seconds. Repeat steps 2 – 4 if two puffs are ordered.

**FIGURE 29.17** Transtracheal oxygen catheter

**FIGURE 29.18** Patient receiving nebulized mist treatment.

**FIGURE 29.19** Instructions for use of a metered-dose inhaler. See package inserts for specific instructions because many types of inhalers are available.
traditional MDI. Use of a spacer can increase the amount of medication that gets to the lungs (Fig. 29.20).

Before December 31, 2008, many MDIs used a chlorofluorocarbon (CFC) as a propellant, but CFC damages the ozone, so new ways to deliver inhaled medications have been developed. Many new models of inhalers such as dry powder inhalers do not use any propellants, and some use an HFA (hydrofluoroalkane) propellant. With so many different types of inhalers, it is important to carefully read the instructions for use before assisting a patient.

The RT or nurse must carefully instruct the patient because improper use can reduce the effectiveness of the medication. It is also important to teach the patient to avoid overuse of adrenergic bronchodilator inhalers. Patients with chronic lung disease may tend to use extra puffs when they feel short of breath. Adrenergic bronchodilators, however, can cause severe rebound bronchoconstriction and even death when used too often.

**Incentive Spirometry**

Incentive spirometers (Fig. 29.21) are used to encourage deep breathing in patients at risk for collapse of lung tissue, a condition called atelectasis. These devices are commonly ordered for postoperative patients. Patients are instructed to use the spirometer 10 times each hour they are awake. Because a variety of spirometers are available, consult with an RT and read package inserts for specific directions for use.

**Chest Physiotherapy**

Chest physiotherapy (CPT), which includes postural drainage, percussion, and vibration, helps move secretions from deep inside the lungs (Fig. 29.22). It is indicated for the patient who has a weak or ineffective cough and is at risk for retaining secretions. Patients with retained secretions due to conditions such as COPD, cystic fibrosis, or bronchiectasis and patients on ventilators benefit from CPT.

CPT is performed by an RT or specially trained nurse. For postural drainage, the patient is placed in various positions (head down to help drain secretions) and turned periodically...
during the treatment so all lobes of the lungs are drained. The therapist uses cupped hands to strike the chest repeatedly (percussion), producing sound waves that are transmitted through the chest, loosening secretions. The therapist may also apply vibration to the patient’s chest, using the hands or a vibrator, to loosen secretions. An NMT should be given before CPT to humidify secretions. The patient is instructed to cough and deep breathe at intervals during and after the treatment.

**High-Frequency Chest Wall Oscillation Vest**

The high-frequency chest wall oscillation vest (sometimes called vest therapy) is an alternative to CPT. Because it does not require the presence of a RT, it is less expensive over time. An inflatable vest is placed on the patient, and a compressor generates pulses of air into the vest to vibrate the patient’s chest. Like CPT, this helps loosen secretions so that they can be expectorated. The patient must cough during and after the therapy for it to be effective. It can easily be used at home.

**Vibratory Positive Expiratory Pressure Device**

Another alternative to chest physiotherapy is a small handheld device called a vibratory positive expiratory pressure (PEP) device. (One brand is the Flutter mucus clearance device shown in Fig. 29.23.) When the patient blows into the mouthpiece, it makes a heavy steel ball inside bounce around in its chamber, which then sends vibrations back into the airways to help loosen mucus. Blowing into the device also creates positive pressure, which opens airways.

**Thoracentesis**

Thoracentesis involves the insertion of a needle into the pleural space. It is commonly done to aspirate fluid in patients with pleural effusion (fluid trapped in the pleural space, see Chapter 31). The procedure may be diagnostic to determine the source of fluid or therapeutic to remove fluid and reduce respiratory distress. It may also be performed to aspirate blood or air or to inject medication.

> When assisting an HCP with a thoracentesis, first verify that the patient understands the procedure and that written consent has been obtained if required by institution policy. Have the patient void before the procedure. The patient should be aware that a sensation of pressure may be felt, but that severe pain is rare. Administer an analgesic, if ordered, before the procedure. Obtain a special procedure tray that has the equipment needed by the HCP. Place the patient in a sitting position, bending over a bedside table, or in a side-lying position if unable to sit. You can position yourself in front of the patient and encourage relaxation during the procedure. If you are asked to hand equipment to the HCP, be sure to keep everything sterile.

> The HCP uses a local anesthetic before inserting a needle into the patient’s back through the desired interspace. Specimens are withdrawn through the needle, labeled, and sent to the laboratory. If the thoracentesis is being done for therapeutic reasons, a sterile container is used to collect the remaining fluid. As much as 2 L can be removed, sometimes more, and the patient will usually report immediate reduction of dyspnea.

> After the procedure, the HCP may apply a petroleum jelly dressing to prevent air leakage into the wound. Assess vital signs, breath sounds, and the puncture site according to the HCP’s orders (e.g., every 15 minutes times two, every 30 minutes times two, then every 4 hours for 24 hours). The patient is usually maintained on bedrest for 1 hour after the procedure. Label and send specimens to the laboratory as ordered. The HCP may order a postprocedure x-ray examination to ensure that the lung was not punctured, causing a pneumothorax.

**Chest Drainage**

Continuous chest drainage involves insertion of one or two chest tubes by the HCP into the pleural space to drain fluid or air. The tubes are connected to a chest drainage system that collects the fluid or allows escape of the air.

**Indications**

Chest tubes and a chest drainage system are used when fluid or air has collected in the pleural space. This can occur with a collapsed lung (pneumothorax), pleural effusion, penetrating chest injury, or during chest surgery. These conditions are covered in Chapter 31.

Chest Tube Insertion

The HCP inserts drainage tubes through the chest wall into the pleural space either in surgery or at the bedside. If removal of air from around a collapsed lung is the goal, the tube is inserted into the upper anterior chest, in the second to fourth intercostal space. If removal of fluid is the goal, such as after an injury, the tube is inserted in the lower lateral chest, in the eighth or ninth intercostal space. If a patient has both air and fluid to drain, two tubes are inserted and may be joined with a Y connector before connecting to the tubing that leads to a drainage system.

You can assist the HCP by obtaining a chest tube insertion tray and chest drainage system and preparing it according to the manufacturer’s directions. Ensure that the patient understands the procedure and that written consent has been obtained according to institutional policy. Administer an analgesic as ordered, and help position the patient as directed by the HCP. Chest tube insertion is often an emergency intervention, which necessitates preparing the patient quickly.

Once the tube has been inserted and the system is in place, ensure that each connection is securely taped to prevent a break in the system. Petroleum jelly gauze and a sterile occlusive dressing are applied over the insertion site to prevent air leakage. If the dressing becomes soiled, do not change it; reinforce it with additional dressings, and notify the RN or HCP. Some nurses may change chest tube dressings with special training.

Obtain two padded clamps to keep at the bedside. These are used for clamping the chest tube if the chest drainage system becomes accidentally disconnected from the tubing, for changing the drainage system, or for a trial period before chest tube removal. The tubes are never clamped for more than a few seconds, however, because this prevents air escape and can cause a buildup of air in the pleural space. This can create a tension pneumothorax, which is a life-threatening emergency (see Chapter 31).

Chest Drainage System

The drainage system has evolved from a set of glass bottles to a one-piece molded plastic system with chambers that correspond to the bottles. Studying the bottle system will help you understand the one-piece system (Fig. 29.24). One, two, or three bottles can be used. Study the picture as you read the following sections.

WATER SEAL BOTTLE OR CHAMBER. Each time the patient exhales, trapped air also escapes the pleural space and travels through the chest tube to the water seal bottle or chamber, under the water, and then bubbles up and out of the bottle. The water acts as a seal, allowing air to escape from the pleural space but preventing air from getting back in during the negative pressure of inspiration. When the system is initiated, bubbling will occur on each exhalation until the lung is re-expanded. Once most of the pneumothorax is resolved, water in the tube fluctuates up with each inspiration and down with each expiration, as much as 5 to 10 cm. This is called tidal. When the lung is fully inflated, tidal stops. If tidal stops before the lung is reinflated, the tubing should be checked for a kink or occlusion. If constant bubbling occurs in the water seal chamber, the system should be checked immediately for leaks.

SUCTION BOTTLE OR CHAMBER. Sometimes a suction source is used to speed lung re-inflation. A separate bottle with tubing attached to suction is used. The amount of suction depends on the level of water in the bottle, not the amount of suction set on the machine. (Look at the picture—some air is being suctioned from the atmosphere through the center straw, and some is being suctioned from the patient. The farther the straw is immersed in the water, the harder it will be for the suction to draw air from the atmosphere, and more will be suctioned from the patient.) The suction level is ordered by the HCP and is almost always negative 20 cm of water. The suction source should be turned on far enough to cause gentle bubbling in the suction bottle or chamber. Vigorous bubbling causes water evaporation, which alters the
amount of suction. If water evaporates, more must be added to maintain the correct amount of suction. Some newer one-piece systems use special valves to eliminate the need for water.

**DRAINAGE BOTTLE OR CHAMBER.** Sometimes a third bottle is needed to catch fluid drained from the pleural space. Drainage may be from pleural effusion, chest trauma, or surgery. Sometimes a small amount of drainage occurs because of the insertion of the chest tube. The drainage chamber is not emptied to measure drainage. Rather the drainage level in the bottle or chamber is marked and timed each shift to monitor the amount. It is documented as output on the intake and output record. If drainage suddenly increases or becomes very bloody, notify the HCP. If the drainage chamber fills up, either the chamber or the entire unit will need to be changed, depending on the type of system used.

**Nursing Care of the Patient With a Chest Tube**

Nursing care of a patient with a chest tube involves regular assessment of the patient and the drainage system. See Box 29-1 for specific assessment and care. If permitted by the HCP, patients can be free to move around with the chest tube and drainage system. The drainage system must always be kept upright and below the level of the chest. If the patient must be transported, the drainage system is transported with the patient. Ask the HCP if the patient can be safely transported without suction. If the answer is yes, the suction control chamber is then left open to allow air to escape. Do not clamp tubing for transport.

If a chest tube is accidentally pulled out before the pneumothorax is resolved, air can re-enter the pleural space. Some HCPs want an occlusive dressing placed over the site to prevent air from re-entering. However, an occlusive dressing increases the risk of trapped air building up and placing pressure on the heart. Contact the RN or HCP immediately if this occurs.

**Stripping and Milking**

In the past, it was routine to strip or milk the tubing from the patient toward the drainage system to dislodge clots and maintain patency. Stripping is done by holding the proximal end of the tubing and using the other hand to squeeze the tubing between two fingers while sliding the fingers toward the drainage system. This is repeated on small sections of tubing until all have been stripped. It is now known, however, that this process can create negative pressure at the openings in the tubing that are within the pleural space, which can suck lung tissue in and cause damage. Stripping should be done only if it is ordered by the HCP and even then only with specific instructions.

Milking is done by gently squeezing portions of tubing from the patient to the system without any sliding motion. This is somewhat safer for the patient but is still not done routinely. If tubing appears to be occluded, consult with the HCP for specific orders.

---

**Box 29-1 Care of the Patient With a Chest Drainage System**

Assess the patient according to institution policy. Start with the patient and move toward the drainage system.

**PATIENT**

1. Observe respiratory rate, effort, and symmetry.
2. Assess shortness of breath, pain, anxiety, or other discomforts.
3. Auscultate lung sounds (lung sounds may initially be muffled or absent on the side of a collapsed lung but should gradually return to normal as the lung reinflates).
4. Confirm that dressing is intact; observe for drainage. If necessary, reinforce the dressing and notify the HCP. Do not change the dressing unless specifically ordered to and trained to do so.
5. Palpate around insertion sites for crepitus.

**TUBING**

6. Check all tubing for kinks, breaks, or broken connections. Verify that all connections are securely taped.
7. Ensure that there are no dependent loops of tubing. Excess tubing should be coiled on the bed.

**DRAINAGE SYSTEM**

8. Verify that drainage system is below level of patient’s chest at all times.
9. Check drainage system for cracks or leaks.
10. Check water seal chamber for correct water level and for tidaling (unless lung is reinflated). Add water if evaporation has decreased level. If continuous bubbling is present, check entire system for leaks and notify HCP.
11. Check suction control chamber for gentle bubbling (or open to air). Confirm correct amount of water as ordered. Add water if needed.
12. Check and mark amount of drainage in collection chamber every 8 hours and prn or as ordered. Report any marked increase in bloody drainage. Record drainage as output.

*Notify RN or HCP if any of the following occur:*

- The patient suddenly reports increasing dyspnea.
- There is a change in the patient’s assessment findings.
- The drainage chamber is full and needs to be changed.
Removal of Chest Tube

When the reason for the chest tube is resolved, the HCP removes it and places petroleum jelly gauze and a sterile occlusive dressing over the site. Continue to watch for development of crepitus and monitor the patient’s respiratory status and dressing site.

Tracheostomy

A tracheotomy is a surgical opening through the base of the neck into the trachea. It is called a tracheostomy when it is more permanent and has a tube inserted into the opening to maintain patency (Fig. 29.25). The patient breathes through this opening, bypassing the upper airways. A tracheostomy is performed for a variety of reasons, such as in patients who have had a cancerous larynx removed, patients with airway obstruction caused by trauma or a tumor, patients who have difficulty clearing secretions from the airway, or patients who need prolonged mechanical ventilation.

The tracheostomy tube consists of three parts: an outer cannula, an inner cannula, and an obturator (Fig. 29.26A and B). The obturator is a guide that is used only during insertion of the tube. After insertion, the obturator is immediately removed.

CRITICAL THINKING

Miss Israel

Miss Israel has a chest tube in place for a spontaneous pneumothorax.

1. You note that the water seal chamber is bubbling vigorously. What could cause this? What should you do?
2. You are totaling intake and output for your 8-hour shift. There is 240 mL of serous fluid in the drainage chamber of the drainage system at 2200. At 1400, there was 190 mL. How much output should you record?

Suggested answers are at the end of the chapter.

and kept at the bedside (commonly in a plastic bag taped to the wall above the bed) for emergency use if the tracheostomy tube is accidentally removed. The outer cannula remains in place at all times and is secured by ties to prevent dislodging. The inner cannula is removed at intervals, usually every 8 hours and as needed for cleaning. Some newer tracheostomy tubes eliminate the need for an inner cannula.

The tube may be metal or plastic. Plastic tubes typically have disposable inner cannulas, which can be replaced rather than cleaned. Plastic tubes also may have balloon-like cuffs that are inflated to prevent air escape during mechanical ventilation. You know that the cuff is inflated if the small pilot balloon on the tube used to inject air is inflated (Fig. 29.26B and C). Cuffs are deflated routinely to prevent tissue damage. See the “Tracheostomy Care Procedure” on DavisPlus for steps required for a routine tracheostomy cleaning.

Communication is problematic for the patient with a tracheostomy tube because air is diverted out the tube rather than past the vocal cords and out the mouth. Fenestrated tubes are tubes with openings (fenestra) in the cannula to allow air to flow up into the larynx for speaking (see Fig. 29.26C). The patient can be taught to plug the opening of the tube while speaking to divert air through the fenestra. Another option is a valve such as the Passy-Muir® tracheostomy speaking valve (Fig. 29.27). This is a special valve that allows air into the tracheostomy during inspiration but closes and redirects air up around the tracheostomy tube, through the vocal cords, and out the nose and mouth on expiration, allowing the patient to speak. Use of the valve eliminates the need for the patient to use a finger over the opening to speak. For the valve to be used safely and effectively, the tracheostomy tube must be small enough for air to flow around it or it must be fenestrated to allow air to flow up through the vocal cords. If cuffed, the cuff must be completely deflated. A patient with a tracheostomy tube in place due to laryngectomy surgery will not have vocal cords, and the trachea will no longer connect to the nose and mouth. The patient will not be able to plug the tube or use a valve to talk; plugging a laryngectomy tube would cause suffocation. Laryngectomy is covered in Chapter 30.

Some tracheostomies are permanent. However, some patients can be weaned from the tracheostomy tube when their condition has improved enough to allow breathing without it. The HCP may replace the tube with a smaller tube to prepare the patient for its removal. This allows a plug to be inserted into the tracheostomy tube at intervals to force the patient to breathe around the tube through the nose and mouth. When the tracheostomy tube has been removed, the opening may be taped shut and covered with gauze until it is healed. The gauze often becomes saturated with secretions and is changed as needed.

**Suctioning**

Suctioning involves the use of a flexible catheter to remove secretions from the respiratory tract of a patient who is unable to cough effectively. This may be a patient with overwhelming secretions or a patient with a tracheostomy or endotracheal tube who is unable to clear the tube with coughing.

The procedures for suctioning are found on DavisPlus. A procedure manual should be consulted for more detailed instruction. Remember that suctioning is both frightening and uncomfortable for a patient. Patients sometimes feel as though oxygen is being “vacuumed” from their lungs. Suctioning can cause hypoxia, vagal stimulation with resulting bradycardia, and even cardiac arrest. It is done only when necessary rather than on a routine basis. Coughing is the most effective way to clear secretions and should be encouraged if the patient is capable. Signs that suctioning is needed include crackles or wheezes heard with or without a stethoscope or a dropping oxygen saturation value. Each step should be explained to the patient during suctioning even if he or she is unresponsive.

**Critical Thinking**

**Mr. Smith**

Mr. Smith had a plastic, cuffed tracheostomy tube that was small enough to allow airflow around it for talking when the cuff was deflated. A friend stopped by for a chat and assisted Mr. Smith to plug his tracheostomy so he could talk. Mr. Smith’s face turned dark red, and his expression showed extreme anxiety.

1. What happened?
2. How could you help prevent this in the future?
3. How would you document this occurrence?

*Suggested answers are at the end of the chapter.*

**Nursing Process for the Patient With a Tracheostomy**

See the “Nursing Care Plan for the Patient With a Tracheostomy.”

---

**Figure 29.27** The Passy-Muir® tracheostomy speaking valve allows air into the tracheostomy during inspiration but closes and redirects air up through the vocal cords and out the nose and mouth on expiration, allowing the patient to speak. Courtesy of Passy-Muir, Inc., Irvine, CA.
NURSING CARE PLAN for the Patient With a Tracheostomy

**Nursing Diagnosis:** Risk for Ineffective Airway Clearance related to excessive secretions

**Expected Outcome:** The patient’s airway will be free of secretions as evidenced by no audible crackles or wheezes in airway and a clear cannula.

**Evaluation of Outcome:** Is airway free of secretions?

**Intervention** Assess lung sounds every 4 hours and as needed (prn). **Rationale** Coarse crackles or wheezes may indicate secretions in airways. **Evaluation** Are coarse crackles or wheezes present?

**Intervention** Monitor oxygen saturation every 4 hours and prn. **Rationale** Secretions may reduce gas exchange. **Evaluation** Is oxygen saturation less than 90%, indicating a problem?

**Intervention** Encourage patient to deep breathe and cough as able. **Rationale** Patients may be able to clear own secretions without suctioning. **Evaluation** Is patient able to cough up secretions effectively?

**Intervention** Encourage fluids if not contraindicated. **Rationale** Fluids help hydrate secretions, making them easier to cough up. **Evaluation** Is patient taking adequate fluids? Are secretions thin?

**Intervention** Provide humidified oxygen or a room humidifier. **Rationale** Humidification helps prevent drying of mucosa and secretions. **Evaluation** Are mucosa moist and secretions easily removed?

**Intervention** Encourage ambulation as able, or turn every 2 hours. **Rationale** Movement helps mobilize secretions. **Evaluation** Is patient mobilized as much as possible?

**Intervention** Clean tracheostomy according to agency policy. **Rationale** Cleaning helps remove excess mucus and keeps airway clear. **Evaluation** Does cleaning help maintain an open airway?

**Intervention** Suction patient using sterile technique, only when needed. **Rationale** Suctioning clears secretions from airways. Unnecessary suctioning irritates airways. **Evaluation** Is suction necessary? Is airway free of secretions after suctioning?

**Intervention** Monitor and document amount, color, and character of secretions. Report change in secretions accompanied by fever. **Rationale** Purulent sputum accompanied by fever can indicate pneumonia. **Evaluation** Is sputum clear or white and scant in amount? Is purulent sputum reported?

**Nursing Diagnosis:** Risk for Infection related to bypass of normal respiratory defense mechanisms and increased aspiration risk

**Expected Outcome:** The patient will be free of infection, as evidenced by vital signs within normal limits and clear secretions.

**Evaluation of Outcome:** Is patient free from symptoms of infection?

**Intervention** Monitor and report signs and symptoms of infection: fever, increased respiratory rate, purulent sputum, elevated white blood cell (WBC) count. **Rationale** Early recognition and treatment of infection enhances outcome. **Evaluation** Are signs of infection present?

**Intervention** Use good hand hygiene practice. **Rationale** Hand hygiene is important in preventing infection. **Evaluation** Do all caregivers use good hand hygiene technique?

**Intervention** Protect tracheostomy opening from foreign material: food, sprays, powders. **Rationale** Foreign materials in the tracheostomy can cause pneumonia. **Evaluation** Is tracheostomy adequately protected?
**NURSING CARE PLAN for the Patient With a Tracheostomy—cont’d**

**Intervention** Use meticulous sterile technique for all tracheostomy care and suctioning. **Rationale** Use of non-sterile technique may introduce microorganisms into the respiratory tract. **Evaluation** Is sterile technique used by all caregivers?

**Intervention** Encourage a well-balanced diet. Consult dietitian prn. **Rationale** A well-balanced diet enhances immune function. **Evaluation** Is patient eating a balanced diet or receiving adequate supplementation?

**Intervention** Keep head of bed elevated 30 to 45 degrees. **Rationale** Elevation helps reduce aspiration of gastric contents, which can lead to pneumonia. **Evaluation** Is head of bed elevated?

**Intervention** Consult with speech therapist and HCP about whether to have cuff inflated or deflated on cuffed tube. **Rationale** An inflated cuff can impair swallowing in some patients, and help prevent aspiration in others. **Evaluation** Is cuff properly inflated or deflated according to specific orders?

**Nursing Diagnosis:** Impaired Verbal Communication related to presence of tracheostomy tube

**Expected Outcomes:** The patient will use alternate methods of communication effectively. The patient will express satisfaction with ability to communicate needs.

**Evaluation of Outcomes:** Is patient able to use alternative methods to express needs? Does patient express satisfaction with ability to do so?

**Intervention** Take time to allow patient to communicate needs. **Rationale** Patient may become frustrated if hurried. **Evaluation** Does patient feel he or she is given adequate time for communication of needs?

**Intervention** Watch for patient’s nonverbal cues. **Rationale** Gestures and facial expression can provide valuable cues. **Evaluation** Is the patient attempting to communicate with nonverbal cues?

**Intervention** Offer pen and paper or magic slate (if patient is literate). **Rationale** The patient may be able to write out his or her needs/concerns. **Evaluation** Is patient able to write out needs?

**Intervention** Use picture board (available from speech therapy department). **Rationale** The patient can point to a picture (water, toileting) that indicates his or her need. **Evaluation** Is patient able to point appropriately to needs?

**Intervention** Teach patient with fenestrated or small tracheostomy tube how to cover opening with a plug or clean finger to talk, or to use Passy-Muir valve, according to HCP or speech therapy recommendations. **Rationale** Covering opening or using valve diverts air into larynx and allows speech. **Evaluation** Is patient able to communicate in this manner?

**Intervention** Consult with speech therapist. **Rationale** Speech therapist may have additional methods for communicating with patient. **Evaluation** Are alternative methods effective?

**Nursing Diagnosis:** Disturbed Body Image related to presence of tracheostomy

**Expected Outcomes:** The patient will verbalize acceptance of tracheostomy. Patient will be willing to participate in tracheostomy care.

**Evaluation of Outcomes:** Does patient verbalize acceptance of tracheostomy? Does patient participate in learning to care for tracheostomy?

**Intervention** Assess patient’s and family members’ feelings about tracheostomy. **Rationale** Assessment provides basis for care. **Evaluation** Are the patient’s feelings within an expected range for such a change in body image? Are family members accepting?
Intubation

Some patients are unable to breathe effectively and maintain adequate oxygenation because of airway obstruction or respiratory failure. These patients are intubated with a special endotracheal (ET) tube through the nose or mouth and into the trachea (Fig. 29.28). Patients in cardiopulmonary arrest are intubated during advanced cardiac life support, and patients undergoing general anesthesia during surgery are intubated. Most intubated patients are also mechanically ventilated. Some patients have advance directives that indicate they do not wish to be intubated. You should be familiar with the patient’s wishes and bring them to the attention of the HCP if necessary.

Because intubation can damage the vocal cords and surrounding tissues, it is usually a short-term intervention. Patients who need long-term ventilatory support have a tracheostomy tube placed.

Nursing Care for the Intubated Patient

Nursing care of the intubated patient includes regular assessment of the patient’s respiratory status and tube placement. Lung sounds are auscultated bilaterally to ensure that the tube has not been displaced into one bronchus. The tube is carefully secured with tape or a Velcro holder to avoid dislodging. Oral tubes are repositioned and resecured to the opposite side of the mouth every 24 hours or according to institution policy to prevent tissue damage. An adhesive skin barrier should be applied under the tape to protect the skin. If the patient is alert, he or she is instructed to be careful not to pull on the tube. You may need to obtain an order for soft wrist restraints if absolutely necessary for the confused patient. Restraints can be avoided if a family member is available to sit with the patient. Many nursing interventions for the patient with a tracheostomy are also appropriate for...
the intubated patient. (See the “Nursing Care Plan for the Patient With a Tracheostomy.”)

Endotracheal tubes have a cuff (a balloon-like area around the tube) to help maintain proper placement and to prevent leakage of air around the tube. An RT usually inflates the cuff and maintains a specific cuff pressure and should be consulted for assistance with this activity.

Patients with ET tubes may need suctioning if they are unable to cough effectively. Visible secretions in the tube, crackles or wheezes heard with or without the stethoscope, or a drop in SaO₂ without another obvious cause are signs that suctioning is necessary. The ET tube suctioning procedure is sterile and is the same as suctioning a tracheostomy tube. Some institutions have in-line suctioning devices, which are connected to the ET tube within a sterile sleeve. This maintains sterility, protects the nurse, and simplifies the suctioning procedure. Oral suction may also be necessary to keep the mouth free of secretions.

The intubated patient is often extremely anxious, especially if she or he is alert. Explain the purpose of all care activities. Suctioning is a particularly anxiety-producing activity and should be explained carefully even if the patient is unresponsive.

Intubated patients are at risk of developing ventilator-associated pneumonia (VAP) because normal respiratory defense mechanisms are bypassed. Good hand hygiene and frequent mouth care to reduce risk of aspirating oral microorganisms can help prevent VAP. The head of the bed should also be kept elevated 30 to 45 degrees at all times.

Because the ET tube passes between the vocal cords, the patient is unable to speak. Provide paper and pencil or a picture board for communication. Yes/no questions can be answered by a nod or shake of the head.

Monitor arterial blood gas and oxygen saturation values and notify the HCP of changes. If oxygen values drop or the patient becomes confused or agitated, the patient should be immediately assessed for a disconnected oxygen source or excessive secretions.

If the HCP determines that the patient can breathe effectively without the tube, the tube will be removed. The patient will be slowly weaned from the ventilator first. Before tube removal, the patient’s mouth and tube are suctioned, and the cuff is deflated. After removal, the patient is observed closely for laryngeal edema or respiratory distress. The patient is maintained in high Fowler’s position to maximize chest expansion.

Mechanical Ventilation

Ventilators are devices that provide ventilation (respirations) for patients who are unable to breathe effectively on their own (Fig. 29.29). Ventilators use positive pressure to push oxygenated air via a cuff-fed ET or tracheostomy tube into the lungs at preset intervals. Patients may need mechanical ventilation after some surgeries, after cardiac or respiratory arrest, for declining arterial blood gases related to worsening respiratory disease, or for neuromuscular disease or injury that affects the muscles of respiration.

Ventilator Modes

Ventilators can control ventilation or assist the patient’s own respirations. See Table 29.9 for terms related to ventilator...
Ventilator Alarms

Several types of alarms are found on ventilators. Low-pressure alarms sound if the ventilator senses reduced pressure in the system. This can be caused by disconnected tubing, leaks in tubing or around the ET tube, or an underinflated cuff. A low-pressure alarm may also sound if the patient has attempted to remove the tube.

High-pressure alarms sound for higher-than-normal resistance to airflow. This might occur if the patient needs to be suctioned; if the patient is biting on the tube, coughing, or trying to talk; if tubing is kinked or otherwise obstructed; or if worsening respiratory disease causes decreased lung compliance. In addition, the high-pressure alarm may be triggered if the patient is anxious and unable to time his or her breaths with those of the ventilator. Water in the tubing might also cause a high-pressure alarm. Consult with the respiratory care department for guidance in draining the tubing.

A loss-of-power alarm may signal a power failure or a disconnected plug. Be aware of emergency power sources and be prepared to ventilate the patient manually if necessary.

Volume and frequency alarms sound when tidal volume or number of breaths per minute fall outside preset parameters. When an alarm sounds, always check the patient first. If the patient is stable, the machine may be checked. Determine why the alarm is sounding and correct the problem quickly. If no cause can be found, disconnect the patient from the ventilator and call for help. Use a manual resuscitation bag until help arrives.

NURSING CARE. Before initiating mechanical ventilation, it is important for the health care team to be aware of any advance directives and consult with the patient and family, because many patients do not wish to be intubated and mechanically ventilated. Some patients accept mechanical ventilation if it is a temporary measure but not if it might be a permanent intervention.

Until recently, ventilators were used only in intensive care units. Now ventilators are seen on medical-surgical units, in nursing homes, and even in patients’ homes. It is important that a team approach be used when caring for a patient who is mechanically ventilated. The social worker; RT; physical, occupational, and speech therapist(s); dietitian; nurse; and HCP all work together to provide the comprehensive care needed by the patient. RTs usually take responsibility for routine monitoring and equipment maintenance.

The nurse is responsible for monitoring the patient, ensuring that ventilator settings are maintained as prescribed, providing initial response to alarms, keeping tubing free from water accumulation, and keeping the patient’s airway free from secretions. In addition, the nurse keeps a manual resuscitation bag at the bedside for emergencies. Good nursing care is essential for preventing ventilator-associated complications, especially pneumonia. Keep the head of the bed at a 45-degree angle to reduce the risk of aspiration. Oral care with 0.12% chlorhexidine solution can significantly reduce the incidence of VAP (Zurmehly, 2013). Regular suctioning helps keep the airway clear. Good nutrition is also essential and has been shown to be related to eventual successful weaning.

Patients who are mechanically ventilated are unable to talk and can become very uncomfortable and anxious if there is no easy way to communicate. See Box 29-2 for one nurse’s tips for making ventilated patients feel more secure. These tips were developed after the author interviewed 12 patients who had been intubated. They shared their fears, anxieties, and physical discomforts.

function. There are many types and models of ventilators. Consult with the respiratory care department for an explanation of a patient’s ventilator and how to troubleshoot alarms.

Ventilator Alarms

Several types of alarms are found on ventilators. Low-pressure alarms sound if the ventilator senses reduced pressure in the system. This can be caused by disconnected tubing, leaks in tubing or around the ET tube, or an underinflated cuff. A low-pressure alarm may also sound if the patient has attempted to remove the tube.

High-pressure alarms sound for higher-than-normal resistance to airflow. This might occur if the patient needs to be suctioned; if the patient is biting on the tube, coughing, or trying to talk; if tubing is kinked or otherwise obstructed; or if worsening respiratory disease causes decreased lung compliance. In addition, the high-pressure alarm may be triggered if the patient is anxious and unable to time his or her breaths with those of the ventilator. Water in the tubing might also cause a high-pressure alarm. Consult with the respiratory care department for guidance in draining the tubing.

A loss-of-power alarm may signal a power failure or a disconnected plug. Be aware of emergency power sources and be prepared to ventilate the patient manually if necessary.

Volume and frequency alarms sound when tidal volume or number of breaths per minute fall outside preset parameters. When an alarm sounds, always check the patient first. If the patient is stable, the machine may be checked. Determine why the alarm is sounding and correct the problem quickly. If no cause can be found, disconnect the patient from the ventilator and call for help. Use a manual resuscitation bag until help arrives.

NURSING CARE. Before initiating mechanical ventilation, it is important for the health care team to be aware of any advance directives and consult with the patient and family, because many patients do not wish to be intubated and mechanically ventilated. Some patients accept mechanical ventilation if it is a temporary measure but not if it might be a permanent intervention.

Until recently, ventilators were used only in intensive care units. Now ventilators are seen on medical-surgical units, in nursing homes, and even in patients’ homes. It is important that a team approach be used when caring for a patient who is mechanically ventilated. The social worker; RT; physical, occupational, and speech therapist(s); dietitian; nurse; and HCP all work together to provide the comprehensive care needed by the patient. RTs usually take responsibility for routine monitoring and equipment maintenance.

The nurse is responsible for monitoring the patient, ensuring that ventilator settings are maintained as prescribed, providing initial response to alarms, keeping tubing free from water accumulation, and keeping the patient’s airway free from secretions. In addition, the nurse keeps a manual resuscitation bag at the bedside for emergencies. Good nursing care is essential for preventing ventilator-associated complications, especially pneumonia. Keep the head of the bed at a 45-degree angle to reduce the risk of aspiration. Oral care with 0.12% chlorhexidine solution can significantly reduce the incidence of VAP (Zurmehly, 2013). Regular suctioning helps keep the airway clear. Good nutrition is also essential and has been shown to be related to eventual successful weaning.

Patients who are mechanically ventilated are unable to talk and can become very uncomfortable and anxious if there is no easy way to communicate. See Box 29-2 for one nurse’s tips for making ventilated patients feel more secure. These tips were developed after the author interviewed 12 patients who had been intubated. They shared their fears, anxieties, and physical discomforts.
of the invasive endotracheal or tracheostomy tube, NIPPV uses an external masklike device that fits over the nose or mouth and nose (Fig. 29.30). It can be successful in patients who are alert, able to cooperate, do not have excessive secretions, and are able to breathe on their own for periods of time. It can be used with or without supplemental oxygen. In an acutely ill patient, oxygen saturations are monitored.

Two basic types of NIPPV are available: continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP). With CPAP, the same amount of positive pressure is maintained throughout inspiration and expiration to prevent airway collapse. In BiPAP, a lower level of positive pressure is used on expiration.

Problems to be alert for in patients receiving NIPPV include skin irritation from the mask and gastric distention from swallowing air. Apply an adhesive skin barrier to the areas that come in contact with the mask to prevent irritation. To prevent gastric distention, place the patient in semi-Fowler’s position and consult with the RT to adjust air delivery pressure if necessary. Topical saline or a special humidifier on the machine can reduce nose and mouth dryness. An air leak around the mask can cause air to blow in the patient’s eyes, which can be irritating. If this happens, remove the mask and reposition it. Another problem is patient acceptance of NIPPV. Many patients do not like the tight mask covering their nose or mouth. Be patient in explaining the reason for this treatment and check the patient frequently to help control anxiety. Be sure to assess the patient’s goals for therapy. Some patients may choose not to use NIPPV, but they must be fully aware of possible consequences.

Patients can use NIPPV nearly continuously, removing it to eat or use the bathroom. Other patients who are able to breathe effectively on their own during the day use it only when they are sleeping. Some use it for a few days until an acute exacerbation of disease is resolved, and others continue its use indefinitely at home.

**Box 29-2 Tips for Caring for Patients Who Are Mechanically Ventilated**

- Mechanically ventilated patients report feeling panicky but less so if relatives or nursing staff are present.
- Speak to the patient each time you enter the room and explain everything you do.
- Encourage family to visit.
- Answer the patient’s call light and attend to ventilator alarms promptly.
- Use restraints only as a last resort.
- Patients may have difficulty relaxing and sleeping while on a ventilator.
- Administer sedatives or antianxiety drugs as ordered. Request an order if necessary.
- Allow uninterrupted blocks of time for sleep.
- Patients with endotracheal tubes report pain and discomfort.
- Assess for comfort and reposition at regular intervals.
- Be careful not to pull on the ventilator tubing.
- Administer analgesics as ordered.
- Provide good oral care, moistening the lips with a cool washcloth and water-based lubricant.
- Suctioning is painful and frightening for patients.
- Suction quickly and smoothly, and avoid inserting the catheter too deeply.
- Avoid the use of saline with suctioning, which can reduce \( \text{SpO}_2 \).
- Allow the patient to suction him or herself if possible (with HCP order and appropriate instruction).
- Communication is very difficult for the patient.
- Be patient when trying to understand communication efforts.
- Provide a pencil and paper, but be aware that even writing can be exhausting.
- Ask yes or no questions when possible. Establish a response system with the patient such as blinking (once for no, twice for yes), hand squeezes, or nodding.
- Validate patient expressions and body language; don’t assume that a patient is sad or wants to be left alone based on facial expression.
- Make sure the call light is within reach at all times.

**Noninvasive Positive-Pressure Ventilation**

Noninvasive positive-pressure ventilation (NIPPV) is an alternative to intubation and mechanical ventilation for patients who are able to breathe on their own but are unable to maintain normal blood gases. Patients with severe respiratory disease, sleep apnea, or neuromuscular diseases such as amyotrophic lateral sclerosis (ALS) that weaken respiratory muscles can benefit from this treatment. Instead
CRITICAL THINKING

■ Timothy

1. There is no way to know whether Timothy needs to be in the emergency room without further assessment. Remember that shortness of breath is very subjective and must be evaluated before discharge.

2. Collect further data. Have Timothy rate his shortness of breath. Look at his color and use of accessory muscles. Check his vital signs, peak expiratory flow rate, and oxygen saturation.

3. If Timothy is having an asthma attack, one explanation for the absence of wheezing on auscultation is that he is not moving enough air to generate the wheezing sound. If his airways are extremely tight, breath sounds may be so diminished that wheezing is not heard. This is a bad sign rather than a good one.

4. If Timothy’s assessment findings are abnormal, call for help. The HCP may want to begin treatment quickly before further evaluation is done. A RT can be helpful with both further assessment and treatment. Collaborate with the RN to determine the cause of Timothy’s problems and provide appropriate education to prevent repeat episodes.

■ Miss Israel

1. Bubbling in the water seal chamber indicates a leak in the system. Vigorous bubbling may indicate a large leak, and the HCP should be contacted immediately. After you check the patient, check the entire system for cracks or leaks and correct any problems discovered.

2. 50 mL.

■ Mr. Smith

1. Mr. Smith plugged his tracheostomy while the cuff was still inflated, so no air could get to his lungs. If the plug is not removed immediately, he will be totally unable to breathe. Whenever the plug is in place, air must be able to travel around the tracheostomy tube or through the opening of a fenestrated tube so the patient can breathe.

2. To prevent this from happening in the future, Mr. Smith should be taught how his tracheostomy tube works and how to care for it. He can be taught to check the pilot balloon if he is unsure.

3. “Answered call for help at 12:30, found patient dark red in color, unable to breathe, trach plugged. Trach unplugged, respirations restored, vital signs stable. Patient stated he plugged trach so he could talk to his friend. Function of trach cuff explained to patient and friend. Both verbalize understanding to only plug trach when cuff is deflated or to call for nurse if unsure.”

REVIEW QUESTIONS

1. How should the nurse record smoking history on a patient who has smoked 2.5 packs of cigarettes per day for 10 years?
   1. Patient has smoked cigarettes for 10 years.
   2. Patient smokes 2.5 packs of cigarettes per day.
   3. Patient has a 12.5 pack-year smoking history.
   4. Patient has a 25 pack-year smoking history.

2. Which term should be used to document the musical sounds generated by airflow through narrowed airways?
   1. Crackles
   2. Wheezes
   3. Friction rub
   4. Stridor

3. Which laboratory result should alert the nurse to perform further assessment on a patient admitted with respiratory distress?
   1. PaCO₂ <50 mm Hg
   2. HCO₃⁻ <27 mEq/L
   3. PaO₂ <90 mm Hg
   4. SpO₂ <90%

4. Place the following steps in the correct sequential order for obtaining a sputum specimen for culture.
   1. Have the patient cough deeply from the lungs.
   2. Teach the patient to inhale deeply several times.
   3. Check the order for the test.
   4. Send the specimen immediately to the laboratory.
   5. Obtain the appropriate container.
5. Which instruction is correct when teaching a patient how to use a traditional metered-dose inhaler?
1. “Inhale deeply, place canister in mouth, depress top of canister, exhale.”
2. “Exhale, place canister in mouth, depress canister and inhale at the same time.”
3. “Cough, place canister in mouth, inhale deeply, cough again.”
4. “Exhale, depress canister, place in mouth, inhale deeply.”

6. A patient with a continuous positive airway pressure (CPAP) mask develops dry irritated eyes from the blowing air. What nursing intervention will help prevent eye irritation while maintaining the positive pressure ventilation?
1. Offer moisturizing eyedrops.
2. Discontinue the CPAP.
3. Reposition the mask.
4. Tape the patient’s eyes closed.

Answers can be found in Appendix C.

Nursing Care of Patients With Upper Respiratory Tract Disorders

PAULA D. HOPPER

LEARNING OUTCOMES

1. Explain the pathophysiologies of disorders of the upper respiratory tract.
2. Describe etiologies, signs, and symptoms of disorders of the upper respiratory tract.
3. Describe current therapeutic measures for disorders of the upper respiratory tract.
4. Plan nursing care for the patient with an upper respiratory disorder.
5. Discuss how you will know if your care has been effective.
6. Identify the special needs of the patient who has undergone a laryngectomy.

KEY TERMS

dysphagia (dis-FAY-jee-oh)
epistaxis (EP-iss-TAX-iss)
exudate (EKS-yoo-dayt)
laryngectomee (lare-in-JEK-tuh-mee)
laryngitis (lare-in-JY-tiss)
myalgia (my-AL-jyah)
nasoseptoplasty (NAY-zoh-SEP-toh-plahstee)
pharyngitis (fair-in-JY-tiss)
rhinitis (rye-NYE-tiss)
rhinoplasty (RY-noh-plahstee)
sinusitis (SY-nuss-EYE-tuss)
Disorders of the upper respiratory tract include problems occurring in the nose, sinuses, pharynx, larynx, and trachea. Many of these problems are minor illnesses that can be cared for at home. Others can become serious if they are not recognized and treated in a timely manner.

**DISORDERS OF THE NOSE AND SINUSES**

**Epistaxis**

**Pathophysiology**

Epistaxis is more commonly known as a nosebleed. The nose can bleed either from the anterior or posterior region. Anterior bleeds are much more common and originate from a group of vessels called the Kiesselbach plexus. Anterior bleeds are easier to locate and treat than posterior bleeds. The blood vessels of the posterior nose are larger, and bleeding can be severe and difficult to control.

**Etiology**

The most common cause of epistaxis is dry, cracked mucous membranes. Trauma, forceful nose blowing, nose picking, and tumors are also factors. Anything that reduces the blood’s ability to clot, such as hemophilia or leukemia, regular aspirin use, anticoagulant therapy, or chemotherapy can predispose a patient to nosebleeds. Cocaine use can also cause epistaxis. High blood pressure can prolong a nosebleed but is not usually the cause.

**Therapeutic Measures**

Instruct a patient with a nosebleed to sit in a chair and lean forward slightly to avoid aspirating or swallowing blood. If the patient swallows blood, it will be difficult to assess the extent of bleeding, and it might cause nausea and vomiting. Be sure to wear gloves and follow standard precautions. Place pressure on the nares for 5 to 10 minutes to stop bleeding. However, avoid placing pressure on the nose if a fracture is suspected to avoid further trauma. Ice packs to the nose and eye area may be used to constrict the bleeding vessels.

If first aid measures are ineffective in stopping bleeding, a physician may attempt more invasive treatment. Local application of a vasoconstrictive agent such as oxymetazoline (Afrin) or phenylephrine might be used to constrict the bleeding vessels. If the bleeding vessel can be located, the physician may cauterize it by use of an electrical cauterizing device or by application of silver nitrate.

Gauze may be used to pack the anterior nasal cavity. The cavity is packed firmly but gently, usually with half-inch petroleum or iodoform gauze. Placement and removal of packing can be uncomfortable for the patient. If there is time, administration of an analgesic before the procedure is helpful. Petroleum jelly on the packing helps prevent gauze from adhering to the nasal mucosa. If the packing is to remain in place for several days, it is coated with an antibiotic ointment to reduce the risk of infection, or oral antibiotics may be ordered.

Commercial products such as compressed sponges and nasal tampons are available to pack the nose. For anterior and posterior bleeds, balloon catheters such as the Rapid Rhino® device can be inserted and inflated near the bleeding vessels in the nasal cavity (Fig. 30.1). The inflated balloon places pressure on the bleeding vessels to stop the bleeding. A small Foley catheter can also be used for this procedure. If these measures are not effective, materials such as a gelatin sponge or a tiny coil can be inserted into the bleeding artery. Patients who are treated for posterior bleeding are typically hospitalized until they are stable.

If the patient has lost a significant amount of blood, intravenous (IV) fluid replacement or a transfusion may be needed. Nosebleeds rarely cause death because blood loss lowers blood pressure, which in turn slows the bleeding. Ultimately the cause of the epistaxis is determined and corrected if possible. Rarely, surgical correction may be necessary for repeat episodes of epistaxis.

**Nursing Care for the Patient With Epistaxis**

Monitor bleeding, noting the amount and color of drainage. Monitor vital signs and hemoglobin level for signs of excessive blood loss. If the patient swallows repeatedly, inspect the back of the throat for bleeding. If bleeding does not stop within 10 to 15 minutes, or if it worsens, notify a registered nurse (RN) or health care provider (HCP) immediately.

If posterior packing has been used, monitor the patient for airway obstruction from a slipped device. Know how to remove
Nasal Polyps

**Pathophysiology and Etiology**

Polyps are grapelike clusters of mucosa in the nasal passages. They are usually benign, but they can obstruct the nasal passages and are sometimes complicated by sinus infections. Although the exact cause is unknown, they are related to chronic inflammation, and people with allergies are prone to developing them. They are also associated with cystic fibrosis. Some patients with nasal polyps also have asthma and are allergic to aspirin. This is called **aspirin triad asthma** because the three components often occur together.

**Therapeutic Measures**

Control of allergy symptoms may help control polyp development. Oral antihistamines or nasal corticosteroid sprays can help control inflammation. Antibiotics are used if there is a related sinus infection. If polyps obstruct breathing, they can be removed. This is done as an outpatient procedure under local anesthesia, using laser or endoscopic surgery. Patients are taught to avoid aspirin products after surgery. They are also advised to avoid bending over, which can increase pressure in the nose. If the cause of the bleeding is dryness, teach the patient to use nasal saline spray or a room humidifier.

**Nasoseptoplasty**

Nasoseptoplasty can be done. This surgery involves revising or removing the deviated portion of the septum. Nasal packing is then placed to reduce bleeding. This is typically done as an outpatient surgical procedure under local anesthesia.

**Signs and Symptoms**

The patient may report a chronically stuffy nose or discomfort from blocked sinus drainage. Some patients have headaches, sinus infections, or nosebleeds.

**Therapeutic Measures**

Symptoms may be treated with decongestants, antihistamines, or intranasal cortisone sprays to reduce inflammation. However, if the deviated septum is causing chronic problems, a **nasoseptoplasty** can be done. This surgery involves revising or removing the deviated portion of the septum. Nasal packing is then placed to reduce bleeding. This is typically done as an outpatient surgical procedure under local anesthesia.

**Rhinoplasty**

**Rhinoplasty** is the surgical reconstruction of the nose, usually for cosmetic purposes. It may also be done to correct deformity caused by trauma. Nursing care is similar to that for the patient after nasoseptoplasty.

**Sinusitis**

**Pathophysiology and Etiology**

**Sinusitis** is inflammation of the mucosa of one or more sinuses. It can be either acute or chronic. Chronic sinusitis is diagnosed if symptoms have existed for more than 3 months and are unresponsive to treatment. The maxillary and ethmoid sinuses are the most commonly affected. The inflammation is often the

---

**CRITICAL THINKING**

**Mr. Jondahl**

Mr. Jondahl is brought to the emergency room with a nosebleed. His vital signs are blood pressure 140/90 mm Hg, pulse 92 beats per minute, respirations 20 per minute. He states that he has never had a nosebleed before. He denies any history of coagulation disorders. His current medications include captopril (Capoten), furosemide (Lasix), and ibuprofen (Motrin). What are two areas you should assess further in trying to determine a cause? (Hint: If you are not familiar with Mr. Jondahl’s medications, look them up.)

Suggested answers are at the end of the chapter.

---

**WORD BUILDING**

nasoseptoplasty: naso—nose + septo—septum + plasty—to mold, as in plastic surgery

rhinoplasty: rhin—nose + plasty—to mold, as in plastic surgery

sinusitis: sinus—sinus + itis—inflammation
result of a bacterial infection and may follow a cold or other viral upper respiratory illness. Because the mucous lining of the nose and sinuses is continuous, nasal organisms easily travel to the sinuses. When the infected mucous lining of the sinuses swells, drainage is blocked. Bacteria that normally reside in the sinuses multiply in the retained secretions. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Other causes of sinusitis include swelling caused by allergies, nasal polyps, fungal infection, or intubation with a nasotracheal or nasogastric tube.

**Signs and Symptoms**

The patient usually has pain over the region of the affected sinuses and purulent nasal discharge. If a maxillary sinus is affected, the patient will have pain over the cheek and upper teeth. In ethmoid sinusitis, pain occurs between and behind the eyes. Pain in the forehead typically indicates frontal sinusitis. Fever may be present in acute infection, with or without generalized fatigue and foul breath.

**Complications**

The patient who has received inadequate treatment or who has not complied with treatment is at risk for complications. Uncontrolled sinusitis may spread to surrounding areas, causing osteomyelitis, cellulitis of the orbit (infection of the soft tissues around the eye), abscess, or meningitis. Sinusitis can also trigger asthma symptoms.

**Diagnostic Tests**

Uncomplicated sinusitis may be diagnosed based on symptoms alone. If repeated episodes occur, x-ray examination, nasal endoscopy, computed tomography (CT) scan, or magnetic resonance imaging (MRI) may be done to confirm the diagnosis and determine the cause. Nasal discharge may be cultured to determine appropriate antibiotic therapy.

**Therapeutic Measures**

Treatment is aimed at relieving pain and promoting sinus drainage. Nasal irrigation with normal saline solution helps some sufferers of chronic sinusitis. Corticosteroids, usually via a nasal spray (such as fluticasone [Flonase]) reduce inflammation. Adrenergic nasal sprays such as oxymetazoline (Afrin) constrict blood vessels and therefore reduce swelling, but they should be used cautiously by patients with heart disease or hypertension because vasoconstriction increases blood pressure. Adrenergic sprays may be used for up to 3 days; longer use may cause rebound congestion. Warm moist packs over the affected sinus for 1 to 2 hours twice a day may help decrease inflammation. Acetaminophen or ibuprofen is given if pain is severe. Expectorants such as guaifenesin (Robitussin, Mucinex), fluids, and a room humidifier can help loosen secretions. Antihistamines dry and thicken secretions and usually are avoided. Antibiotics are not recommended for most sinus infections. If conservative treatment does not relieve symptoms, the physician may surgically drain the affected sinus and irrigate it with normal saline or an antibiotic solution.

One such drainage procedure is the Caldwell-Luc procedure. The surgeon enters the maxillary sinus above the upper teeth, under the upper lip. The infected mucosa and bone are removed, and a new, larger opening is made to drain the sinus. Newer procedures, now more common, use nasal endoscopy to open and drain a chronically infected sinus.

**Nursing Care for the Patient With Sinusitis**

Patients with uncomplicated sinusitis are cared for at home. Instruct the patient to increase water intake to 8 to 10 glasses per day unless contraindicated. Excess water might be contraindicated in patients with fluid overload, such as those with cardiovascular or kidney disease. Pressure may be relieved if the patient maintains a semi-Fowler’s position, as in a reclining chair. Explain the use of arm moist packs, analgesics, and prescribed medications. Instruct the patient to finish the antibiotic prescription even if he or she is feeling better before it is completed and to call the primary care provider if pain becomes severe or if signs of complications such as a change in level of consciousness occur.

**Sleep Apnea**

**Pathophysiology and Etiology**

The patient with obstructive sleep apnea (OSA) has periods of apnea during sleep. This most often occurs when sleeping supine. The muscles of the throat relax, and the tongue and soft tissues fall back to obstruct the airway (Fig. 30.2). Transient hypoxemia results, and a signal to take a breath causes a sudden, loud inhalation. This can occur up to 100 times an hour throughout the night. Men are affected more often than women, as are people who are overweight, smokers, and...
those with high arched palates or receding jawlines. OSA is associated with increased risk for heart disease, high blood pressure, stroke, and diabetes.

**Signs and Symptoms**

Ask the sleeping partner of someone with sleep apnea, and he or she will tell you that sleep apnea is noisy. When the tongue falls back and obstructs the airway, the result is total silence. When breathing resumes, it is like a very loud snore. Spouses often find themselves lying awake waiting for the next breath. Because the quality of sleep is impaired, the sufferer may awaken with a headache, often is not rested on awakening, is sleepy throughout the day, and may have difficulty with memory and attention. Sudden sleepiness can make driving dangerous.

**Diagnostic Tests**

A sleep study involves an overnight stay at a sleep center. (The proper name for this test is nocturnal polysomnography.) The patient is hooked up to electroencephalogram (EEG), electrocardiogram (EKG), electromyography (EMG), oxygen saturation, and eye movement monitors and then observed while sleeping. Many people find it somewhat difficult to fall asleep hooked up to so many wires, but a sedative would alter the results of the test. A less sophisticated form of the test can sometimes be performed at home.

**Therapeutic Measures**

Teach patients self-care measures such as avoiding alcohol or sedatives at bedtime; these can worsen apnea by increasing relaxation of the muscles in the pharynx. Advise against sleeping on the back, and encourage smoking cessation. Weight loss may help reduce sleep apnea and is also a good idea for reducing cardiovascular and diabetes risks. A newer treatment involves nasal patches (such as Provent®) that have valves that impede airflow on exhalation, causing increased pressure in the airway. This holds the airway open during exhalation.

New evidence-based guidelines from the American College of Physicians provide three treatment recommendations: (1) weight loss, (2) noninvasive positive pressure ventilation (NIPPV, see Chapter 29), and (3) use of a mandibular advancement devices (a mouthpiece to advance the mandible). If all other measures have failed, surgery may be necessary to remove excess tissue.

**Nursing Care Tip**

If your patient has trouble avoiding sleeping on his back, have him sew a pocket onto the back of an old tee shirt and put a tennis ball in it. As soon as he rolls over onto the ball, he’ll quickly be back on his side!

**Infectious Disorders**

Viral Rhinitis/Common Cold

**Pathophysiology and Etiology**

Rhinitis (also called coryza) is inflammation of the nasal mucous membranes. The release of histamine and other substances causes vasodilation and edema. It may occur as a
reaction to allergens (sometimes called hay fever) such as pollen, dust, molds, or some foods, or it may be caused by viral or bacterial infection. Viral rhinitis is another name for the common cold. The most common cold virus is the rhinovirus, which is contagious.

**Signs and Symptoms**
Common symptoms include nasal congestion, localized itching, sneezing, sore throat, and nasal discharge. Viral or bacterial rhinitis may also be accompanied by fever and malaise. Sometimes it is difficult to differentiate between a cold and influenza (flu). See Table 30.1 for signs and symptoms of each.

**Diagnostic Tests**
A throat culture or rapid flu test can help identify whether symptoms are caused by the flu virus.

**Therapeutic Measures**
Treatment of viral rhinitis is symptomatic. Because colds are caused by viruses, antibiotics are not effective. Inappropriate use of antibiotics can lead to antibiotic-resistant infections. Explain to the patient that taking antibiotics for a viral infection is not only ineffective but also potentially dangerous.

Acetaminophen can be used for generalized discomfort. Decongestants cause vasoconstriction, which reduces swelling and congestion. Any drugs that cause vasoconstriction should be used cautiously in patients with heart disease or hypertension. Cough syrups and cold medicines should be used with caution, because they do not treat the underlying cause of the cold and often contain several drugs, many of which are not really needed. Teach the patient that rest and fluids are the most effective treatment (see the “Nursing Care Plan for the Patient With an Upper Respiratory Infection”). Echinacea, vitamin C, and zinc are alternative remedies that might help reduce the severity or length of symptoms by supporting the immune system, but there is not enough evidence to be sure at this time.

**EVIDENCE-BASED PRACTICE**

**Clinical Question**
Are antibiotics useful for the common cold or purulent rhinitis?

**Evidence**
Eleven research studies were reviewed. Researchers found that patients receiving antibiotics did not do better than those receiving placebos and had higher risk for adverse effects.

**Implications for Nursing Practice**
Routine use of antibiotics for the common cold or purulent rhinitis is not recommended.

Pharyngitis
Pathophysiology and Etiology
Pharyngitis, or inflammation of the pharynx, is usually related to bacterial or viral infection. It may also occur as a result of trauma to the tissues. Five percent to 15% of pharyngitis cases are caused by beta-hemolytic streptococci, commonly referred to as strep throat. If strep throat is not treated with antibiotics, it can lead to rheumatic fever, glomerulonephritis, or other serious complications.

Signs and Symptoms
The most common symptom of pharyngitis is a sore throat. Some patients may also experience dysphagia (difficulty swallowing). The throat appears red and swollen, and exudate (drainage or pus) may be present. Exudate usually signifies bacterial infection and may be accompanied by fever, chills, headache, and generalized malaise.

Diagnostic Tests
The HCP may order a rapid streptococcal antigen test or a throat culture and sensitivity test (explained in Chapter 29) to identify the causative organism and determine which antibiotic will be effective.

Therapeutic Measures
If the pharyngitis is bacterial, antibiotics are ordered. Penicillin is commonly used for streptococcal infection. Acetaminophen or throat lozenges may be used to relieve discomfort. Saltwater gargles (a teaspoon salt in a glass of warm water) or honey and lemon mixed with warm water help soothe inflamed tissues. Encourage fluids (if not contraindicated) and rest. (See the “Nursing Care Plan for the Patient With an Upper Respiratory Infection.”)

Laryngitis
Pathophysiology and Etiology
Laryngitis is an inflammation of the mucous membrane lining the larynx (voice box). It can be caused by irritation from smoking, alcohol, chemical exposure, gastroesophageal reflux disease (GERD), or a viral, fungal, or bacterial infection.

NURSING CARE PLAN for the Patient With an Upper Respiratory Infection

Nursing Diagnosis: Impaired Comfort related to infectious process
Expected Outcomes: The patient will be comfortable as evidenced by statement of increased comfort and ability to swallow and sleep at night.
Evaluation of Outcomes: Does the patient express comfort? Is the patient able to sleep?

Intervention Assess for cause of discomfort: malaise, muscle aches, fever, sore throat. Rationale Knowing cause of discomfort helps guide intervention. Evaluation Can interventions be directed toward specific symptoms?

Intervention Offer acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) as ordered. Rationale Analgesics relieve pain. Antipyretics relieve fever, which may contribute to discomfort. Evaluation Do analgesics/antipyretics relieve discomfort?

Intervention Offer throat lozenges, saltwater, or honey and lemon gargles as ordered for irritated throat. Rationale Lozenges or gargles soothe irritated mucous membranes. Evaluation Do measures relieve throat irritation?

Intervention Encourage rest. Rationale Physical stress increases need for sleep. Rest boosts immune function. Evaluation Is patient resting comfortably?

Nursing Diagnosis: Hyperthermia related to infectious process
Expected Outcomes: The patient will have a temperature lower than 103°F (39.4°C) and show no signs/symptoms of dehydration.
Evaluation of Outcomes: Is the patient’s fever controlled at safe level? Is the patient well hydrated?
It often follows an upper respiratory infection. Laryngeal cancer can also cause symptoms of laryngitis.

**Signs and Symptoms**
The most common symptom is hoarseness. Cough, dysphagia, or fever may also be present.

**Diagnostic Tests**
The HCP may use a tiny mirror to view the larynx. If hoarseness persists for more than 2 weeks, a laryngoscopy and biopsy may be done to rule out cancer of the larynx.

**Therapeutic Measures**
Treatment includes rest, fluids, humidified air, and aspirin (in adults) or acetaminophen. Antibiotics are used if bacterial infection is present. Medication to control acid reflux is used if GERD is the cause. Encourage the patient to avoid speaking, which will help rest the voice. Also advise the patient that whispering strains the voice even more than normal speech. Obtain a “magic slate” (from the speech therapy department) or paper and pen to help the patient communicate. Throat lozenges may help increase comfort. Help the patient to identify and avoid causative factors. (See the

</table>
Tonsillitis/Adenoiditis
Pathophysiology and Etiology
The tonsils are masses of lymphoid tissue that lie on each side of the oropharynx. They filter microorganisms to protect the lungs from infection. Tonsillitis occurs when the filtering function becomes overwhelmed with a virus or bacteria and infection results. The adenoids, a mass of lymphoid tissue located at the back of the nasopharynx, can also become involved. Tonsillitis is more common in children but is more serious when it occurs in adults. Tonsillitis is usually viral, but bacteria that are commonly associated with tonsillitis include *Streptococcus* species, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pneumococcus* species.

Signs and Symptoms
Tonsillitis usually begins suddenly with a sore throat, fever, chills, and pain on swallowing. Generalized symptoms include headache, malaise, and myalgia. On examination, the tonsils appear red and swollen and may have yellow or white exudate on them. If the adenoids are involved, the patient may mention snoring, a nasal obstruction, and a nasal tone to the voice.

Diagnostic Tests
A throat culture is done to discover the causative organism and determine effective treatment. A white blood cell count and differential can also help identify whether the infection is viral or bacterial. A chest x-ray may be done if respiratory symptoms are present.

Therapeutic Measures
Antibiotics are prescribed for bacterial infection. Acetaminophen, lozenges, and saline gargles help promote comfort. For care of the patient who is not having a tonsillectomy, see the “Nursing Care Plan for the Patient With an Upper Respiratory Infection.”

If tonsillitis becomes chronic or if breathing or swallowing is affected, a tonsillectomy may be considered, although this is not a common procedure in an adult. An adenoidectomy may be performed at the same time. After the tonsillectomy, the patient is maintained in a semi-Fowler’s position to reduce swelling and promote drainage. Monitor the patient for bleeding and airway patency, and provide comfort measures. Encourage fluids for hydration; cold fluids may help reduce pain and bleeding. Red-colored drinks are avoided because they interfere with observation for bleeding. A room humidifier helps prevent drying. Keep suction equipment available for emergencies.

Influenza
Pathophysiology and Etiology
Influenza, commonly called the flu, is a viral infection of the respiratory tract. Many different flu viruses have been identified, and new strains appear each year. Influenza is the cause of millions of lost workdays each year. Young children, chronically ill patients, and older adults are at particular risk for complications and even death from influenza because of compromised immune function.

Influenza is easily transmitted via droplets from coughs and sneezes of infected people, or it may be transmitted by physical contact with a person or object that harbors the virus. The incubation period from time of exposure to onset of symptoms is 1 to 3 days.

Prevention
The Centers for Disease Control and Prevention (CDC) recommends a yearly flu vaccine for anyone over 6 months of age (2013). Although Medicare covers the cost of a flu shot, many older adults do not get one. Emphasize to older people that they will not get the flu from the shot because it does not contain any live virus. Once the shot has been administered, it takes about 2 weeks for antibodies to develop; it is then effective for about 4 months. Other important preventive measures include hand hygiene and avoidance of people with influenza.

Signs and Symptoms
Symptoms of flu include abrupt onset of fever, chills, myalgia, sore throat, cough, general malaise, and headache. Flu can last for 2 to 5 days, with malaise lasting up to several weeks.

CRITICAL THINKING
Mrs. Hiler
- You are caring for Mrs. Hiler after a tonsillectomy. She is sleeping, but you notice that she swallows every few seconds. She has an IV line of normal saline solution running at 100 mL per hour.
  1. How do you respond?
  2. What should you be vigilant for?
  3. How many drops per minute do you set on her IV if the tubing has a drop factor of 15?

Suggested answers are at the end of the chapter.
Complications

The most common complication of influenza is pneumonia, which may be caused by the same virus as the flu or by a secondary bacterial infection. This should be suspected if the patient has persistent fever and shortness of breath or if the lungs develop crackles or wheezes.

Diagnostic Tests

Viral cultures of throat or nasal swabbing can be done to identify influenza, but results may take 3 to 10 days. Rapid tests can identify the presence of flu virus in less than 15 minutes in an office setting but are less reliable than cultures. Cultures may also be done to rule out bacterial infection. Once influenza has been identified in a geographical area, HCPs will test less often and treat based on symptoms.

Therapeutic Measures

Treatment is primarily symptomatic. Acetaminophen is given for fever, headache, and myalgia. Aspirin is avoided in children because it increases the risk of Reye’s syndrome. Rest and fluids are essential. Antibiotics are used only if a secondary bacterial infection is present.

Antiviral medications such as zanamivir (Relenza, an inhaled agent) and oseltamivir (Tamiflu, an oral medication) may reduce the severity and duration of symptoms if given within 48 hours of becoming ill. Antiviral agents may also be given prophylactically to high-risk people who have not been immunized or to control outbreaks in high-risk situations, such as in long-term care facilities.

Nursing Care for the Patient With Influenza

Older adults or other high-risk patients may be hospitalized for treatment of influenza. These patients are closely monitored for complications. Assess lung sounds and vital signs every 4 hours and monitor for dehydration. Report changes to an RN or HCP. Encourage rest and fluids (if not contraindicated), and provide supportive measures. Teach patients and families not to give aspirin to treat influenza symptoms in children aged under 18 years because of the risk of Reye’s syndrome. (See the “Nursing Care Plan for the Patient With an Upper Respiratory Infection.”)

For an excellent tutorial for you or your patients, visit www.nlm.nih.gov/medlineplus/tutorials/influenza/htm/index.htm.

Other Viral Infections

In recent years, new viruses have become a worldwide concern. Several of these are described in this section. Continuous research is being conducted to learn more about the spread, prevention, and treatment of new viral infections.

Bird Flu

Avian influenza, more commonly known as bird flu, is an influenza virus that infects wild and domestic birds (often poultry), just as people get infected by the flu. Humans can contract it from contact with infected birds or their secretions or excrement. Transmission does not occur from eating infected poultry and eggs as long as they have been properly prepared and cooked. Eggs from infected poultry typically do not make it to stores. Transmission from human to human is rare, but is a potential concern.

Symptoms of bird flu are similar to the influenza symptoms described earlier, but complications can be more severe and deadly. Conventional vaccines are not effective in preventing bird flu. Oseltamivir (Tamiflu) may be useful in treatment, along with supportive measures.

SARS

Severe acute respiratory syndrome (SARS) is another newer viral disease that has influenza-like symptoms. High fever, body aches, and respiratory symptoms often progress to pneumonia. SARS first appeared in Asia in 2003. Transmission is believed to occur from close contact with a contaminated person or object or through respiratory droplets when an ill person coughs or sneezes. SARS is treated with antiviral medications, steroids, and oxygen.

Swine Flu

The H1N1 and H3N2 viruses cause what is commonly known as the swine flu. It was first recognized in humans in 2009. It is called swine flu because the virus usually affects pigs, but it is also transmitted to humans and from human to human. It cannot be contracted by eating cooked pork. Symptoms and prevention are similar to those for other types of flu. Seasonal flu vaccines protect against H1N1. Antiviral agents may be used, but no agent is specific to swine flu.

West Nile Virus

West Nile virus is less deadly than some other flu viruses but can still cause serious complications. West Nile virus is transmitted from birds to humans by mosquitoes and causes either no symptoms or flu-like symptoms. However, in a few people,
especially older adults, it can progress to encephalitis (inflammation of the brain) and meningitis (inflammation of the covering of the brain and spinal cord). Teach patients to prevent exposure by using mosquito repellant and to eliminate standing water where mosquitoes lay eggs. There is no specific treatment for West Nile virus. Patients who develop complications are hospitalized for supportive care.

**MALIGNANT DISORDERS**

Cancer of the Larynx

**Pathophysiology**

Cancer of the larynx (the voice box) usually develops in the squamous cells of the mucosal epithelium. It is evaluated based on the tumor-node-metastasis (TNM) staging system described in Chapter 11. It is most often a primary cancer and can spread to the lungs, liver, or lymph nodes. The prognosis for a patient with laryngeal cancer is good with early diagnosis but is often poor because many patients delay seeking help.

**Etiology**

Risk factors for cancer of the larynx include a history of alcohol and tobacco use. Exposure to industrial chemicals or hardwood dust, chronic overuse of the voice, and a diet low in fruits and vegetables are also factors. Men are more likely to be affected than women.

**Prevention**

Prevention begins with education. You can help educate patients about the relationship between cancer of the larynx and use of alcohol and tobacco. It is also important to teach patients to seek help when symptoms first occur because a delayed diagnosis may mean metastasis of the cancer and a poor prognosis. Teach that any hoarseness that lasts longer than 2 weeks should be investigated by a HCP.

**Signs and Symptoms**

The most common symptom is persistent hoarseness because the vocal cords are located in the larynx (Table 30.2). The patient may also have throat or ear pain, shortness of breath, a chronic cough, and difficulty swallowing. Stridor may indicate a tumor obstructing the airway. Late signs include weight loss and halitosis (foul breath).

**Diagnostic Tests**

The larynx can be examined with a laryngeal mirror. Laryngoscopic examination and biopsy are used to diagnose and determine the stage of laryngeal cancer. A CT scan, MRI, or other diagnostic tests may be done to determine the presence or extent of metastasis.

**Therapeutic Measures**

If laryngeal cancer is diagnosed early in the disease, it may be treatable with radiation therapy; this treatment can preserve the patient’s voice. Chemotherapy may be used with radiation or surgery, but it is not usually used alone. New targeted chemotherapy attacks only certain cells in the body. Surgery may be done at any stage of the disease. The larynx will be either partially or completely removed (Fig. 30.3). If cancer has spread beyond the larynx, a radical neck dissection, which removes adjacent muscle, lymph nodes, and tissue, may be done. Surgery can be done using laser technology, endoscopy, or traditional methods.

After a partial laryngectomy, the patient may have a permanently hoarse voice. If a total laryngectomy is done, the patient will have a permanent tracheostomy (in this case called a laryngectomy) tube in place and no voice. The patient will need to learn alternative methods of communication. A person who has had a total laryngectomy is sometimes referred to as a laryngectomee.

Several alternatives for long-term speech exist:

- Esophageal speech involves swallowing air and forming words as the air is regurgitated back up the esophagus.
- Electronic devices are available, which the patient places next to the neck or mouth. These devices use sound vibrations to help the patient form words. UltraVoice®

**WORD BUILDING**

laryngectomee: laryng—larynx + ectome—excision (person who has undergone laryngectomy)
munication skills. Will need support after discharge to continue to develop communication skills. A dietary consult is also important before surgery if the patient has been undernourished.

Consult a speech therapist before surgery to provide a picture of the patient’s understanding of the disease process and self-care needs after surgery. It is important to evaluate the patient’s support systems and ability to cope with the partial or total loss of voice after surgery.

Nursing Process for the Patient Undergoing Total Laryngectomy

PREOPERATIVE CARE. In addition to routine preoperative teaching, the patient undergoing a total laryngectomy surgery must be prepared for the loss of ability to breathe through the mouth and nose and loss of ability to speak. Initial instruction in communication techniques should take place before surgery to prevent the patient from feeling panicked after surgery when he or she cannot communicate needs. A variety of techniques and devices are available. Consult a speech therapist before surgery to provide a picture board, magic slate, or paper and pencil (see Chapter 49). The patient is instructed to point to the picture that corresponds with the need or to write out his or her concern. A dietary consult is also important before surgery if the patient has been undernourished.

LEARNING TIP
Did you ever “burp the ABCs” as a child? If not, ask most any child to demonstrate! This uses the same idea as esophageal speech.

Nursing Diagnoses, Planning, and Implementation

Risk for Ineffective Airway Clearance related to excessive secretions and new tracheostomy/laryngectomy

EXPECTED OUTCOME: The patient will maintain a clear airway as evidenced by clear lung sounds and ability to cough up secretions.

- Monitor and record amount, color, and consistency of secretions; vital signs; oxygen saturation; lung sounds; and signs of respiratory distress. Visible secretions, a drop in oxygen saturation (SpO2), or an increase in crackles may indicate airway compromise and a need for suctioning. A change in amount or color of secretions, an increased temperature, or presence of adventitious sounds can indicate infection and should be reported to the HCP immediately.
- Provide tracheostomy care and suctioning according to agency policy (see Chapter 29). This keeps the airway clear.
- Maintain strict sterile technique with tracheostomy care and suctioning. Prevention of infection is essential, because the airway no longer has the protection of normal upper airway defense mechanisms.
- Place the patient in semi-Fowler’s position to allow for lung expansion and more effective coughing.
- Encourage the patient to deep breathe and cough every hour to keep airway free of secretions.
- Administer oxygen as ordered. A special tracheostomy collar should be used. Supplemental oxygen helps maintain oxygenation. The oxygen must be applied to the stoma because there is no connection between the nose and lungs.
- Provide room or oxygen humidification. Humidification can help keep secretions mobile.
- Avoid use of powders, sprays, or other airborne materials near the patient. These can cause irritation or infection if they enter the laryngectomy.

Acute Pain related to surgical procedure

EXPECTED OUTCOME: The patient will state his or her pain level is acceptable.

- Assess pain level every 4 hours and as needed (prn). A good assessment must guide treatment.
- Assess sedation and respiratory status often. Opioids are given carefully because they may reduce respiratory rate and cough reflex, which is vital to clearing the airway.

POSTOPERATIVE CARE.

Data Collection. Collecting data about the patient’s physical and psychosocial status, comfort, nutritional status, and ability to swallow is important both before and after surgery. After surgery, assessment of airway patency and respiratory function takes priority. Monitor lung sounds, oxygen saturation, and arterial blood gases. In addition, be sure to assess the patient’s understanding of the disease process and self-care needs after surgery.

The patient will state his or her pain level is acceptable.

- Assess pain level every 4 hours and as needed (prn). A good assessment must guide treatment.
- Assess sedation and respiratory status often. Opioids are given carefully because they may reduce respiratory rate and cough reflex, which is vital to clearing the airway.
• Include nonpharmacological pain control interventions (see Chapter 10). Interventions such as distraction and relaxation may help with pain control and reduce (not eliminate) the need for opioids.

• Administer analgesics as ordered, on an around-the-clock basis or via patient-controlled pump, for the first few days after surgery. If the liver has been damaged from previous alcohol use, dosages are adjusted by the HCP. The patient who is comfortable will be better able to participate in care and take measures to prevent complications, such as coughing and ambulating.

**Expected Outcome**

- Use a picture board or paper and pencil so the patient can communicate without speaking.
- Make sure the patient has a call light or bell nearby at all times. Patients can become panicky if they have a need and no way to summon a nurse.
- Work with the speech therapist and HCP to provide the patient with a method of communication that best fits his

---

**FIGURE 30.4** Devices to aid speech in the laryngectomy patient. (A) UltraVoice is an electronic device placed inside a denture or retainer; the patient speaks into a small microphone. Courtesy of UltraVoice Ltd. (B) The Blom-Singer voice prosthesis diverts air into the esophagus and out the mouth to form tracheoesophageal speech. Courtesy of InHealth Technologies, Carpinteria, CA.
UNIT SEVEN Understanding the Respiratory System

or her needs (see Fig. 30.4). Different patients prefer different long-term communication methods.

Risk for Imbalanced Nutrition: Less Than Body Requirements related to absence of oral feeding immediately following surgery and possible previous alcohol use or abuse

**EXPECTED OUTCOME:** The patient’s weight will be within normal limits for height and age.

- Monitor weight. Underweight or weight loss reflects inadequate nutrition.
- Monitor parenteral nutrition or tube feedings after surgery until the neck has begun to heal and swallowing can be evaluated. Nutrition must be maintained to support healing.
- Consult a dietitian for nutrition guidance. If the patient has a history of alcohol abuse, he or she may have been undernourished before surgery. You may need to advocate for the patient and ensure that he or she is receiving adequate calories for healing. A dietitian can assist with specific recommendations.

Impaired Swallowing related to edema or presence of laryngectomy tube

**EXPECTED OUTCOME:** The patient will be able to swallow safely.

- Consult a speech therapist to assist with a swallowing assessment and recommendations. Speech therapists are trained to assess and treat swallowing disorders.
- Assure the patient that aspiration will not occur because there is no longer a connection between the mouth and the lungs.
- Place the patient in high-Fowler’s position to make swallowing easier.
- Stay with the patient during the first attempts to eat to help alleviate anxiety.

Grieving related to loss of voice

**EXPECTED OUTCOME:** Patient will express feelings of loss and begin to plan for the future.

- Assess patient’s feelings of loss. *Inability to speak is a loss that cannot be overemphasized.* The patient may also be facing a career change if job-related exposure contributed to the disease or if loss of voice prevents return to a previously held job.
- Actively attend to the patient’s communication of feelings to show your support and validate feelings.
- Assess and involve support systems. *Family support is important to the patient’s long-term adjustment to a laryngectomy.*
- Contact the patient’s clergy if patient wishes. A religious counselor can help with grief and spiritual distress.

Disturbed Body Image related to change in body structure and function

**EXPECTED OUTCOME:** The patient will verbalize acceptance of new laryngectomy and participate in self-care.

- Portray an accepting attitude. *Patients are very aware of nurses’ nonverbal behavior, and looks of distaste can be disturbing.*
- Allow the patient to share feelings if he or she indicates a need to do so. *This may help the patient to work through feelings about the changes to his or her body image.*
- With the patient’s permission, contact a local support group that may have names of people who have had similar experiences who are willing to visit with the patient. *Such visitors can provide firsthand information and support.*
- Assist the patient to find ways to camouflage the change, such as scarves or necklines that conceal but do not obstruct the airway. *Camouflage can help the patient feel less conspicuous and also protect the airway.*

**EVALUATION.** When evaluating the patient’s progress toward goals, ask the following questions:

- Is the airway clear, without signs of infection or obstruction?
- Does the patient verbalize an acceptable level of comfort?
- Do the patient and significant others demonstrate understanding of self-care at home or have referrals to continue learning self-care at home?
- Does the patient indicate satisfaction with the level and quality of communication?
- Is the patient’s weight stable?
- Is the patient able to swallow if taking oral nutrition?
- Is the patient able to grieve appropriately?
- Does the patient have someone to talk to if he or she wishes?
- Does the patient show acceptance of the laryngectomy by learning to care for it?

Note that many of these evaluative criteria are long term and may not be seen while the patient is hospitalized, so follow-up by a home care nurse is essential.

**PATIENT EDUCATION.** After assessing the patient’s readiness to learn, teach the patient self-care measures for the laryngectomy, including how to perform cleaning and suctioning (see Chapter 29). Involve the significant other or family whenever possible.

The patient must also be instructed to perform gentle range-of-motion exercises of the neck. Some patients may avoid extending the neck because of the location of the incision, causing muscle contracture.

Referral to home nursing after discharge will provide assessment of the home environment, as well as follow-up instruction. A social service referral may be made for financial or psychosocial concerns if needed. Consult with the health care provider or check the local phone directory for laryngectomy support groups, and refer the patient to them if appropriate. The local branch of the American Cancer Society may also be able to provide information. Assist the patient in finding resources to support alcohol and smoking cessation. Continued alcohol and tobacco use will increase the patient’s risk of cancer recurrence.

To find additional information for laryngectomies, visit the National Cancer Institute’s website at www.cancer.gov.
CRITICAL THINKING

■ Mr. Jondahl
Explore the amount of ibuprofen being taken daily because NSAIDs can interfere with platelet aggregation. In addition, high blood pressure can aggravate the bleeding.

■ Mrs. Hiler
1. Mrs. Hiler may be swallowing blood. Examine the back of her throat with a flashlight. Check vital signs for evidence of impending shock. Notify an HCP if bleeding is confirmed.
2. Continue to be vigilant for signs of bleeding: frequent swallowing, or bright red blood from the mouth. Monitor for changes in vital signs and report even small changes to the RN or HCP.
3. Use this formula to determine drops per minute:

\[
\frac{100 \text{ mL}}{1 \text{ hour}} \times \frac{1 \text{ hour}}{60 \text{ minutes}} \times \frac{15 \text{ gtt}}{1 \text{ mL}} = 25 \text{ gtt per minute}
\]

■ Mrs. Murdock
1. Mrs. Murdock may have contracted the flu from a visitor or a staff person at the long-term care facility. She is susceptible because of her age and comorbid conditions (COPD, diabetes).
2. Mrs. Murdock’s flu could probably have been prevented with a flu vaccination, but her son refused it because he believed it could cause her to get the flu. Good hand hygiene by staff and urging visitors not to visit when ill will also help.
3. If it is within 48 hours of symptom onset, an HCP may prescribe an antiviral agent to help reduce her symptoms and shorten the course of her illness. In addition, you can provide fluids, acetaminophen, and comfort measures. You should also monitor her closely for evidence of bacterial infection or pneumonia and report signs or symptoms immediately to the HCP.
4. A major concern is that Mrs. Murdock could transmit the flu to other residents or staff. Hopefully, they have all been vaccinated. In addition, you must decide whether to send Mrs. Murdock to the hospital. Check her advance directives, and talk to her son about goals for her care. If needed, educate him about differences in long-term care and hospital care.
5. Involve the RN, supervisor or director, and infection control nurse. Collaborate to determine how to manage Mrs. Murdock but also to protect other residents.

SUGGESTED ANSWERS TO

REVIEW QUESTIONS

1. Which is the best explanation to a patient by a nurse for why a health care provider does not prescribe antibiotics for influenza?
   1. “Most cases of influenza are caused by antibiotic-resistant bacteria.”
   2. “Influenza is caused by viruses.”
   3. “Antibiotics have too many serious side effects.”
   4. “Antibiotics can interact with other medications used for influenza.”

2. After a laryngectomy, which of the following assessments takes priority?
   1. Airway patency
   2. Nutritional status
   3. Lung sounds
   4. Patient acceptance of surgery

3. Which of the following responses is correct when a patient asks why the health care provider did not order a new antiviral drug for flu symptoms that started 3 days ago?
   1. “Antivirals are for AIDS, not the flu.”
   2. “The side effects of the antiviral drugs are worse than having the flu.”
   3. “Antiviral drugs are only prescribed for children.”
   4. “Antivirals work only if you start them within 48 hours after flu symptoms begin.”

4. Which of the following positions is recommended for a patient experiencing a nosebleed?
   1. Lying down with feet elevated
   2. Sitting up with neck fully extended
   3. Lying down with a small pillow under the head
   4. Sitting up leaning slightly forward
5. The nurse knows that the patient understands teaching related to prevention of influenza transmission when the patient demonstrates which behaviors? **Select all that apply.**
   1. Washing hands frequently
   2. Covering the nose and mouth during coughing or sneezing
   3. Taking acetaminophen as ordered
   4. Drinking extra fluids
   5. Avoiding sharing eating utensils with others
   6. Taking antibiotics until the entire prescription is finished

6. Which of the following communication methods is inappropriate for the patient with a total laryngectomy?
   1. Placing a finger over the stoma
   2. Providing a special valve that diverts air into the esophagus
   3. Obtaining a picture board
   4. Teaching the patient esophageal speech

Answers can be found in Appendix C.

Nursing Care of Patients With Lower Respiratory Tract Disorders

PAULA D. HOPPER

LEARNING OUTCOMES

1. Explain the pathophysiology of each of the disorders of the lower respiratory tract.
2. Describe the etiologies, signs, and symptoms of each of the disorders.
3. Identify tests that are used to diagnose lower respiratory disorders.
4. Describe therapeutic measures used for disorders of the lower respiratory tract.
5. List data to collect when caring for patients with disorders of the lower respiratory tract.
7. Identify interventions for patients experiencing impaired gas exchange, ineffective airway clearance, or ineffective breathing pattern.
8. Explain how you will know if your nursing interventions have been effective.

KEY TERMS

- thoracotomy [THOR-ah-kot-uh-mee]
Disorders of the lower respiratory tract include problems of the lower portion of the trachea, bronchi, bronchioles, and alveoli. These disorders may be related to infection, noninfectious alterations in function, neoplasm (cancer), or trauma. Any pathological condition of the lower respiratory tract can seriously impair carbon dioxide and oxygen exchange.

**INFECTIOUS DISORDERS**

**Acute Bronchitis**

**Bronchitis** is an inflammation of the bronchial tree, which includes the right and left bronchi, secondary bronchi, and bronchioles. When the mucous membranes lining the bronchial tree become irritated and inflamed, excessive mucus is produced. The result is congested airways. Acute bronchitis is usually an isolated episode. If it occurs more than 3 months out of the year for 2 consecutive years, chronic bronchitis is diagnosed. See the discussion of chronic bronchitis later in this chapter for more information that applies to both the acute and chronic forms.

**Bronchiectasis**

**Pathophysiology**

**Bronchiectasis** is a dilation of the bronchial airways (Fig. 31.1). The dilated areas become flabby and scarred. Bronchiectasis can remain localized or spread throughout the lungs. Secretions pool in these areas and are difficult to cough up. This creates an environment where bacteria can flourish, and infection is common.

**Etiology**

Bronchiectasis usually occurs secondary to another chronic respiratory disorder, such as cystic fibrosis, asthma, tuberculosis, bronchitis, or exposure to a toxin. Airway obstruction from a tumor or foreign body can also be a predisposing factor. Infection and inflammation of the airways in these underlying disorders weaken the bronchial walls and reduce ciliary function. Airway obstruction from excessive secretions then predisposes the patient to development of bronchiectasis. Vitamin D deficiency may be related to risk of infection in bronchiectasis, but the mechanism for this link is not clear (Chalmers, 2013).

**Signs and Symptoms**

The patient with bronchiectasis has recurrent lower respiratory infections. Sputum is copious and purulent. The accompanying cough can produce as much as 200 mL of thick, foul-smelling sputum in a single episode of coughing. Interestingly, if the sputum is allowed to sit for a couple of hours, it will separate into a purulent bottom layer, a clear center layer, and a cloudy top layer. Extreme airway inflammation may cause sputum to be bloody. If bronchiectasis is widespread throughout the lungs, the patient may experience dyspnea even with minimal exertion. Wheezes and crackles may be auscultated. Fever is present during active infection. Cor pulmonale (right-sided heart failure; covered in Chapter 26) and clubbing of the fingers may develop with chronic disease.

**Diagnostic Tests**

A chest x-ray examination may be done, but it may not show early disease. A computed tomography (CT) scan provides a better view of the dilated airways. Bronchoscopy may be done if needed. Sputum cultures determine infecting organisms and guide antibiotic therapy. Additional testing may be done to determine the cause of bronchiectasis.

**Therapeutic Measures**

Treatment is aimed at keeping the airways clear of secretions, controlling infection, and correcting the underlying problem. Antibiotics may be used intermittently or for prolonged periods. Azithromycin may reduce exacerbations (Wong et al, 2012). Measures to prevent infection, including vaccinations for flu and pneumonia, should be implemented. **Bronchodilators** improve airway obstruction. **Mucolytic** agents and expectorants help loosen and mobilize secretions so they can be coughed up. Bronchitol, a form of mannitol, is an inhaled drug that is still being studied to promote mucus clearance. It is a sugar that draws fluid into the airways to help liquefy mucus. Inhaled beta-agonist bronchodilators help

**FIGURE 31.1 Bronchiectasis. Note dilated airway.**

**WORD BUILDING**

- **bronchitis**: bronch—airway + itis—inflammation
- **bronchiectasis**: bronch—airway + ectasis—dilation or expansion
- **bronchodilator**: broncho—airway + dilator—to expand
- **mucolytic**: muco—mucus + lytic—break up
Pneumonia

Pneumonia is the cause of many hospital admissions each year and is a common cause of death from infection. Persons at risk for pneumonia are the very young, adults over age 65, and people who are immunocompromised, such as those with acquired immunodeficiency syndrome (AIDS), alcoholism, or another underlying illness. Pneumonia is categorized according to where it is acquired. For example, hospital-acquired pneumonia (HAP) is defined as pneumonia that develops at least 48 hours after a hospital admission. One type of HAP is ventilator-associated pneumonia, or VAP. Health care–associated pneumonia (HCAP) is pneumonia that develops in outpatient settings or nursing homes. Community-acquired pneumonia (CAP) develops in the community and is usually less serious than other forms. Each type of pneumonia may be caused by different organisms.

Pathophysiology

Pneumonia is an acute inflammation and/or infection of the lungs that occurs when an infectious agent enters and multiplies in the lungs of a susceptible person. Infectious particles can be transmitted by the cough of an infected individual, from contaminated respiratory therapy equipment, infections in other parts of the body, or aspiration of bacteria from the mouth, pharynx, or stomach. Organisms from the mouth and pharynx may be related to poor oral hygiene or may be present because of a cold or influenza virus. When pathogens enter the body of a healthy person, normal respiratory defense mechanisms and the immune system prevent the development of infection. In a person who is immunocompromised, however, even microorganisms that are normally present in the oropharynx can cause an infection.

When the microorganisms multiply, they release toxins that induce inflammation in the lung tissue, causing damage to mucous and alveolar membranes. This leads to the development of edema and exudate, which fills the alveoli and reduces the surface area available for exchange of carbon dioxide and oxygen. Some bacteria also cause necrosis of lung tissue.

Pneumonia may be confined to one lobe (lobar pneumonia), or it may be scattered throughout the lungs (bronchopneumonia). Bronchopneumonia occurs more often as a nosocomial infection in hospitalized patients, the very young, or the very old, and can be quite serious. Patients may use terms such as walking pneumonia or double pneumonia. These are not medical terms, but it is helpful to understand them. Walking pneumonia refers to a mild infection that may not even keep the patient from working (or walking); double is a lay term for bilateral.

Etiology

Pneumonia has a variety of causes, as discussed next.

BACTERIAL PNEUMONIA. The most common cause of community-acquired bacterial pneumonia is Streptococcus pneumoniae, also called pneumococcal pneumonia. Other community-acquired infections are caused by Staphylococcus aureus, Chlamydia trachomatis, and Mycoplasma pneumoniae. HAPs are often antibiotic-resistant, and tend to be much more serious than CAP. They can be caused by Escherichia coli, Haemophilus influenzae, and Klebsiella pneumoniae, among others. Methicillin-resistant Staphylococcus aureus (MRSA), Pseudomonas aeruginosa, and other antibiotic-resistant pneumonias are especially difficult to treat.

VIRAL PNEUMONIA. Influenza viruses are the most common cause of viral pneumonia. The presence of viral pneumonia increases the patient’s susceptibility to a secondary bacterial pneumonia. Generally, patients are less ill with viral pneumonia than with bacterial pneumonia, but they may be ill for a longer period because antibiotics are ineffective against viruses.

FUNGAL PNEUMONIA. Candida and Aspergillus are two types of fungi that can cause pneumonia. Pneumocystis carinii pneumonia (PCP) is caused by a fungus and typically causes pneumonia in patients with AIDS.

ASPIRATION PNEUMONIA. Some pneumonias are caused by aspiration of foreign substances. This most often occurs in patients with decreased levels of consciousness or an impaired cough or gag reflex. These conditions can occur with alcohol ingestion, stroke, general anesthesia, seizures, gastroesophageal reflux disease (GERD), or other serious illness. Aspiration pneumonia increases the risk for subsequent bacterial pneumonia.

VENTILATOR-ASSOCIATED PNEUMONIA. A type of aspiration pneumonia, ventilator-associated pneumonia (VAP), develops in patients who are intubated and mechanically ventilated. The endotracheal tube keeps the glottis open, so secretions can be easily aspirated into the lungs. A cuff on the tube is kept inflated to attempt to protect the lower airway, and suction can keep secretions under control, but risk of aspiration is still significant.

HYPOSTATIC PNEUMONIA. Patients who hypoventilate because of bedrest, immobility, or shallow respirations are at risk...
for hypostatic pneumonia. Secretions pool in dependent areas of the lungs and can lead to inflammation and infection.

**CHEMICAL PNEUMONIA.** Inhalation of toxic chemicals can cause inflammation and tissue damage, which can lead to chemical pneumonia. This increases the risk for subsequent bacterial infection.

**Prevention**

Both flu and pneumonia vaccination are essential to preventing pneumonia. See Box 31-1 for current Center for Disease Control and Prevention (CDC) vaccine recommendations.

---

### Box 31-1 2013 CDC Guidelines for Flu and Pneumonia Vaccination

**Flu Vaccine**

Everyone who is at least 6 months of age should get a flu vaccine this season. It’s especially important for some people to get vaccinated. Those people include the following:

- People who are at high risk of developing serious complications like pneumonia if they get sick with the flu. This includes:
  - People who have certain medical conditions including asthma, diabetes, and chronic lung disease.
  - Pregnant women.
  - People 65 years and older.
  - People who live with or care for others who are high risk of developing serious complications. This includes household contacts and caregivers of people with certain medical conditions including asthma, diabetes, and chronic lung disease.

**Pneumococcal Vaccine**

The CDC now recommends two kinds of pneumococcal vaccines for adults.

- One dose of pneumococcal conjugate vaccine (PCV13) is recommended for adults aged 19 years and older with asplenia, sickle cell disease, cerebrospinal fluid leaks, cochlear implants, or conditions that cause weakening of the immune system.
- Adults 19 through 64 years old with certain medical conditions (for example, certain kidney diseases, cigarette smoking, chronic heart or lung disease, asplenia, and conditions that cause weakening of the immune system) should receive one or two doses of pneumococcal polysaccharide vaccine (PPSV23).
- All adults 65 years and older should still get one dose of pneumococcal polysaccharide vaccine (PPSV23).

If you are recommended to get both PPSV23 and PCV13 vaccines, you should get the PCV13 vaccine first, followed by PPSV23 eight weeks later.

---

**Gerontological Issues**

Advanced age is a significant risk factor for serious complications from respiratory infections such as influenza, pneumococcal pneumonia, and aspiration pneumonia. Therefore, it is recommended that people over age 65 and people with chronic disease have yearly influenza vaccines and pneumococcal vaccine with repeat dose as needed. Consistent oral care is also a significant nursing intervention to help prevent morbidity and mortality from aspiration pneumonia.

Nursing care plays an important role in the prevention of HAP. Regular coughing, deep breathing, and position changes for patients on bedrest or after surgery, prevention of aspiration for patients at risk, and good hand hygiene practices by both patients and health care personnel can help prevent many cases (see “Gerontological Issues”).

The risk of VAP can be reduced with frequent mouth care, including toothbrushing, and use of a special endotracheal tube that allows continuous suctioning of secretions above the inflated cuff. All patients should be positioned with the head of the bed elevated 30 to 45 degrees to help prevent aspiration. Medication to reduce gastric acid secretion and stress ulcers may help reduce aspiration but may also increase bacterial growth.

---

### CRITICAL THINKING

**Mr. Smith**

Mr. Smith is an 86-year-old man who was watching television when he couldn’t sleep one night. After seeing a commercial for toilet cleaner, he decided his own toilet could use some attention. He used bleach and ammonia “to get it really clean.” The combination created toxic fumes, which caused a severe chemical pneumonia. He was brought to the emergency room in acute respiratory distress.

1. As his nurse, what questions might you ask as you further assess the cause of his pneumonia?
2. What can you teach Mr. Smith related to prevention of similar episodes in the future?
3. How can you be vigilant in preventing complications in Mr. Smith?

*Suggested answers are at the end of the chapter.*

---

### Signs and Symptoms

Patients with pneumonia present with fever, shaking, chills, chest pain, dyspnea, fatigue, and a productive cough. Sputum is purulent or may be rust-colored or blood-tinged. Crackles and wheezes may be heard on lung auscultation because of the exudate in the alveoli and airways.

---

**WORD BUILDING**

hypostatic: hypo—below + static—standing
Some bacterial and many viral pneumonias cause atypical symptoms. The patient may experience fatigue, sore throat, dry cough, or nausea and vomiting.

Older adult patients may not exhibit expected symptoms of pneumonia. New-onset confusion or lethargy in an older patient can indicate reduced oxygenation and should alert you to look for other symptoms or request evaluation by the health care provider (HCP). New onset of fever or dyspnea should also cause suspicion of pneumonia in older adults.

Complications
Complications from pneumonia most commonly occur in patients with other underlying chronic diseases. Pleurisy and pleural effusion (discussed later in this chapter) are two of the most common complications and generally resolve within 1 to 2 weeks. Atelectasis (collapsed alveoli) can occur as a result of trapped secretions and may be resolved by efforts to keep the airways clear, especially use of an incentive spirometer. Other complications result from spread of infection to other parts of the body, causing septicemia, meningitis, septic arthritis, pericarditis, or endocarditis. Treatment for each of these is antibiotics. Although antibiotics can greatly reduce the incidence of death related to pneumonia, it is still a common cause of death in older people.

Diagnostic Tests
A chest x-ray examination is done to identify the presence of pulmonary infiltrate, which is fluid leakage into the alveoli from inflammation (Fig. 31.2). In addition, sputum and blood cultures are obtained to identify the organism causing the pneumonia and determine appropriate treatment. If the patient is unable to produce a sputum specimen, a nebulized mist treatment may be ordered to promote sputum expectoration. If this is unsuccessful, nasotracheal suctioning or a bronchoscopy can be done to obtain a specimen from a very ill patient.

EVIDENCE-BASED PRACTICE
Clinical Question
Is noninvasive ventilation with oxygen an effective treatment for adult patients with pneumonia?

Evidence
Three randomized controlled trials found that noninvasive ventilation with oxygen in patients with pneumonia reduces risk of death in the intensive care unit (ICU) and may be more beneficial than oxygen alone.
Tuberculosis
Pathophysiology and Etiology

Tuberculosis (TB) is an infectious disease caused by the bacterium *Mycobacterium tuberculosis*. TB primarily affects the lungs, although other areas, such as the kidneys, liver, brain, and bone, may be affected as well. *M. tuberculosis* is an acid-fast bacillus (AFB), which means that when it is stained in the laboratory and then washed with an acid, the stain remains, or stays “fast.” *M. tuberculosis* can live in dark places in dried sputum for months but is killed in a few hours of direct sunlight. It is spread by inhalation of the tuberculosis bacilli from respiratory droplets (droplet nuclei) of an infected person.

Once the bacilli enter the lungs, they multiply and begin to disseminate to the lymph nodes and then to other parts of the body. The patient is then infected but may or may not go on to develop clinical (active) disease. TB infection without disease is called latent TB infection (LTBI). During this time the body develops immunity, which keeps the infection under control. If the lungs are involved, the immune system surrounds the infected area in the lung with neutrophils and alveolar macrophages. This process creates a lesion called a tubercle, which seals off the bacteria and prevents spread. Similar processes take place in other affected areas of the body. The bacteria within the tubercle die or become dormant, and the patient is no longer infectious. If the patient’s immune system becomes compromised, however, some of the dormant bacteria can become active, causing active disease. Only 5% to 10% of infected people in the United States actually develop the disease, and even then it may not occur for many years (see “Gerontological Issues”).

Risk Factors
Crowded or poorly ventilated living conditions place people at risk for becoming infected with tuberculosis. Although tuberculosis can infect any age group, older people are especially at risk. They may have contracted the disease many years before, but it can reactivate as the aging process diminishes immune function. AIDS, chronic alcohol abuse, and cancer chemotherapy can also compromise immune function and increase risk of activation. In the United States, tuberculosis is also prevalent among the urban poor and minority groups.

Before 1985, the incidence of TB in the United States was steadily decreasing. Since that time, it has increased in incidence, in part because of the prevalence of AIDS, the development of antibiotic-resistant strains of the TB bacillus, and ineffective treatment programs. One-third of the world’s population is currently infected with TB (WHO, 2013).

Prevention
Clean, well-ventilated living areas are essential to the health of all people. If a hospitalized patient is known or suspected to have tuberculosis, he or she is placed in respiratory isolation to prevent spread to staff or other patients. Special negative-pressure isolation rooms are ventilated to the outside. Staff should wear special high-ef ficiency filtration masks when in the patient’s room; a regular surgical mask is not effective against TB. Verify with the institution’s infection control department that the masks provided are effective for use with TB patients. If the patient must travel through the hallway for tests or other activities, he or she must wear...
a mask. Additional protective barriers, such as gowns, gloves, or goggles, are used when contact with sputum is likely.

A vaccine against tuberculosis, the Bacillus Calmette–Guérin (BCG) vaccine, is available and is used in areas where TB is prevalent. It is not used routinely in the United States because of the low risk for infection. Individuals who have had the vaccine will have a positive skin test for TB, so alternative methods for screening must be used.

Ultimately, prevention will come from adequate treatment of patients with TB. A current concern is the development of antibiotic-resistant strains of the tuberculosis bacillus, which can develop when patients are noncompliant with drug therapy. When antibiotics are taken intermittently or discontinued early, the more virulent (stronger) bacteria survive and multiply and become resistant to the drugs being used. This multi-drug-resistant TB (MDR-TB) can then be passed on to someone else. Some strains are resistant to nearly all anti-biotics. They are called extensively drug resistant, or XDR-TB. It is therefore vital to teach all patients the importance of strict adherence to drug therapy. Patients who are at risk for nonadherence to drug therapy must have a visiting nurse or other health professional observe each dose of antibiotic taken. This is called directly observed therapy (DOT) or directly observed therapy—short course (DOTS). DOT transfers responsibility for making sure the drugs are taken from the patient to the health care worker. The WHO reports the highest treatment success rates with DOT/DOTS.

In 2006, the WHO launched a global plan to stop TB, with a goal of eliminating it by 2050. The six components of the plan include the following:

1. Pursuing high-quality DOTS expansion
2. Addressing TB in HIV infection, MDR-TB, and other challenges
3. Contributing to health system strengthening
4. Engaging all care providers
5. Empowering people with TB, and communities
6. Enabling and promoting research (WHO, 2013)

**Signs and Symptoms**

Active pulmonary tuberculosis is characterized by a chronic productive cough, blood-tinged sputum, and drenching night sweats. Chest pain, fatigue, poor appetite, weight loss, and a low-grade fever are common. If effective treatment is not initiated, a downhill course occurs, with pulmonary fibrosis, hemoptysis, and progressive weight loss.

**Complications**

Spread of the tuberculosis bacilli throughout the body can result in pleurisy, pericarditis, peritonitis, meningitis, bone and joint infections, genitourinary or gastrointestinal (GI) infection, or infection of many other organs.

**Diagnostic Tests**

Routine screening for tuberculosis infection is usually done with a purified protein derivative (PPD) skin test. The PPD is injected intradermally; the test is considered positive if a raised area of induration occurs within 48 to 72 hours. If a red area appears around the induration, this is not measured. The size of induration that indicates a positive test varies based on the individual’s history (Table 31.2). A red area without induration is considered a negative result. A positive

result indicates that a person has been exposed to TB; it does not mean that active TB disease is present.

Some health care institutions use a two-step process for baseline testing of employees and residents. If an individual has a negative PPD test, he or she is retested in 1 to 3 weeks. This is because someone who was exposed many years ago may not react to the first test. The first test acts as a reminder to the immune system to react. The second test will then be positive in the person with a past TB infection.

**Therapeutic Measures**

Treatment consists of specific antibiotic therapy. First-line drugs have the fewest adverse effects (Box 31-2), but they can still be toxic to the liver and nervous system and have other side effects. Second-line drugs are more toxic and are reserved for cases that do not respond to first-line drug therapy. Generally, two or three antibiotics are given simultaneously to allow lower doses of each individual drug, reducing the incidence of serious side effects, and reducing the risk of developing resistant bacteria. Drugs must be taken for 6 to 9 months or up to 2 years for MDR-TB. Because of the length of therapy and the incidence of side effects, adherence to therapy is often a problem.

Additional treatment is supportive. Rest and good nutrition are important for helping the patient’s own immune system to work. Patients must be isolated until their sputum no longer contains TB bacteria.

Patients with latent TB infection do not need to be treated, but some health departments recommend treatment to reduce the risk of progression to active disease and subsequent spread to others. Latent TB is easier to treat than active TB. The CDC has an excellent website with lots of information about TB at [www.cdc.gov](http://www.cdc.gov). Simply type “tuberculosis” into the search window.

**Nursing Process for the Patient With Tuberculosis**

**DATA COLLECTION.** Perform a thorough history and head-to-toe physical examination, because TB can affect many systems. Focus on respiratory and psychosocial assessments.

---

**Box 31-2 Antibiotics Used to Treat Tuberculosis**

**First-Line Drugs**
- Isoniazid
- Rifampin
- Ethambutol
- Pyrazinamide

**Second-Line Drugs**
- Linezolid
- Rifabutin
- Rifapentine
- Para-aminosalicylic acid
- Streptomycin
- Levofloxacin
- Ethionamide
- Amikacin
- and others
The severity of the disease determines the impact on the patient’s lifestyle. It is also important to determine the patient’s knowledge of the disease and treatment and his or her adherence to drug treatment.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION. Nursing interventions for impaired gas exchange, ineffective airway clearance, and activity intolerance are found in the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder.” Additional nursing diagnoses for the patient with TB follow.

Risk for Ineffective Self Health Management related to deficient knowledge and length of treatment

**EXPECTED OUTCOME:** The patient will follow treatment regimen and infection will be resolved, as evidenced by negative cultures.

- Assess patient’s and family’s ability and intent to follow treatment regimen. It is essential for patients to be diligent about taking their drugs to eradicate the infection and to prevent spread to others.
- Teach patient and family that drugs must be taken as scheduled for the entire course (6 months or longer) or a drug-resistant form of disease may develop. Patients may be more willing to adhere to treatment if they understand the rationale for taking their medications.
- Forewarn the patient that rifampin turns urine and other body fluids red. This might frighten the patient and prevent adherence to treatment.
- Teach patient to report side effects of medications. If side effects can be managed, the patient is more likely to adhere to therapy.
- Request an order for a visiting nurse. A visiting nurse can monitor adherence to therapy. Directly observed therapy (DOT) has been found to increase adherence to medication therapy.

Risk for Infection: Transmission to Others related to deficient knowledge about how infection is spread, or nonadherence to control measures

**EXPECTED OUTCOME:** The patient will verbalize understanding of and employ measures to prevent spreading infection.

- Assess patient’s understanding of how TB is spread.
- Teach patient how TB is spread and the importance of following measures to avoid spread. The patient will be more likely to adhere to prevention measures if he understands the rationale for his actions.
- Teach the patient to use a tissue to cover the mouth and nose when coughing or sneezing. TB is spread by droplet nuclei that can be contained with a tissue.
- Teach patient to flush tissues down the toilet or dispose of carefully in the trash. TB bacteria can live in dried sputum for months, so careful disposal is essential.
- Teach all family members the importance of careful hand hygiene. Hand hygiene is an important measure in preventing all kinds of infections.
- Instruct the patient in the importance of adherence to having follow-up sputum cultures. Once sputum cultures are negative, the patient is no longer contagious.

EVALUATION. If nursing care has been effective, the patient will understand his or her disease and the importance of taking care of himself or herself. The patient will take medications and receive follow-up care as ordered. He or she will take measures to protect others from catching TB. Additional evaluation is found in the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder.”

### NURSING CARE PLAN for the Patient With a Lower Respiratory Tract Disorder

**Note:** The most commonly used nursing diagnoses related to respiratory disorders are presented in the following care plan. This is not a care plan for any one respiratory disorder. Rather, use it as a reference when one of the nursing diagnoses applies to the patient, based on a thorough respiratory assessment.

**Nursing Diagnosis:** Impaired Gas Exchange related to decreased ventilation or perfusion as evidenced by PaO₂ less than 80 mm Hg, PaCO₂ greater than 45 mm Hg, or SpO₂ less than 90%, statement of dyspnea

**Expected Outcomes:** The patient will experience improved gas exchange, as evidenced by improving arterial blood gases (ABGs) or pulse oximetry and statement of acceptable level of dyspnea.

**Evaluation of Outcomes:** Are the patient’s blood gases or SpO₂ improving? Does the patient state that dyspnea is resolved or controlled at an acceptable level?

**Intervention** Monitor arterial blood gas values and pulse oximetry as ordered. **Rationale** PaO₂ less than 80 mm Hg, PaCO₂ greater than 45 mm Hg, or SpO₂ less than 90% indicate impaired gas exchange. **Evaluation** Are values within patient’s baseline values?
**NURSING CARE PLAN** for the Patient With a Lower Respiratory Tract Disorder—cont’d

**Intervention** Assess degree of dyspnea on a scale of 0 to 10, with 0 = no dyspnea and 10 = worst dyspnea. **Rationale** The patient’s subjective report is the best measure of dyspnea; dyspnea indicates impaired gas exchange. **Evaluation** Is patient’s degree of dyspnea within parameters that are acceptable to patient?

**Intervention** Assess lung sounds, respiratory rate and effort, use of accessory muscles. **Rationale** Respiratory rate less than 12 per minute or more than 24 per minute or use of accessory muscles indicates distress. Diminished or adventitious lung sounds can indicate risk factors for impaired gas exchange. **Evaluation** Are lung sounds clear and audible? Is respiratory rate 12 to 20 per minute and unlabored?

**Intervention** Observe skin and mucous membranes for cyanosis. **Rationale** Cyanosis indicates poor oxygenation. Oral mucous membrane cyanosis indicates serious hypoxia. **Evaluation** Are skin and mucous membranes pink?

**Intervention** Monitor for confusion or changes in mental status. **Rationale** Changes in mental status can signal impaired gas exchange. **Evaluation** Is patient alert and oriented? If not, could poor gas exchange be the reason?

**Intervention** Elevate head of bed or help patient to lean on over-bed table. **Rationale** Upright positioning promotes lung expansion. **Evaluation** Did change of position relieve some distress?

**Intervention** Position with good lung dependent (“good lung down”). **Rationale** This position allows the healthier lung to be better perfused and increases gas exchange. **Evaluation** Is SpO2 improved in this position?

**Intervention** Administer supplemental oxygen at ≤ 2 L/min unless ordered otherwise. **Rationale** Supplemental oxygen decreases hypoxia. Rates more than 2 L/min may depress hypoxic drive. **Evaluation** Is oxygen placed properly on patient? Does it provide relief from dyspnea?

**Intervention** Place a fan in the patient’s room, or provide a hand-held fan. **Rationale** The hand-held fan directed toward the face reduces feelings of breathlessness (Galbraith et al, 2010). **Evaluation** Is a fan available to the patient, and does it help?

**Intervention** Teach patient relaxation exercises. **Rationale** Relaxation exercises decrease perceived dyspnea. **Evaluation** Does patient use relaxation effectively?

**Intervention** For chronic disease, teach patient diaphragmatic and pursed-lip breathing. (See Chapter 29.) **Rationale** Breathing exercises promote relaxation and increase CO2 excretion. **Evaluation** Does patient use breathing exercises correctly? Do they help?

**Intervention** Encourage patient to stop smoking if patient is a current smoker. **Rationale** Smoking is damaging to lungs and respiratory function. **Evaluation** Is patient receptive to smoking cessation? Are resources available?

**Intervention** For severe dyspnea, ask HCP about an order for IV morphine sulfate. **Rationale** Low doses of IV morphine reduce anxiety and cause peripheral vasodilation, which helps relieve pulmonary edema. **Evaluation** Does morphine provide relief from dyspnea?

**Nursing Diagnosis:** Ineffective Airway Clearance related to excessive secretions as evidenced by crackles or wheezes, ineffective cough

**Expected Outcome:** The patient will have improved airway clearance as evidenced by clear breath sounds and ability to cough up secretions.

**Evaluation of Outcome:** Are the patient’s breath sounds clear? Is the patient able to effectively cough up and expectorate secretions?
NURSING CARE PLAN for the Patient With a Lower Respiratory Tract Disorder—cont’d

*Continued*
NURSING CARE PLAN for the Patient With a Lower Respiratory Tract Disorder—cont’d

**Intervention** Teach patient to use diaphragmatic breathing, with a regular 2 second in, 4 second out pattern.  
**Rationale** Breathing exercises promote relaxation and increase CO₂ excretion.  
**Evaluation** Is the patient able to demonstrate an effective breathing pattern?

**Nursing Diagnosis:** Activity Intolerance related to imbalance between oxygen supply and demand as evidenced by dyspnea or drop in SpO₂ with routine activity

**Expected Outcomes:** The patient will tolerate increasing activity level as appropriate based on prognosis, as evidenced by stable respiratory rate and SpO₂ with activity. The patient will receive assistance with self-care until he or she is able to carry out own activities of daily living (ADLs) and will space rest and activity to provide as much self-care as possible.

**Evaluation of Outcomes:** Are the patient’s care needs met by self or caregiver?

**Intervention** Assess amount of activity the patient can tolerate without becoming short of breath.  
**Rationale** Patients should be encouraged to do as much as they can for themselves to avoid becoming deconditioned.  
**Evaluation** What is patient able to do?

**Intervention** Monitor vital signs and oxygen saturation with activities.  
**Rationale** Respiratory rate will rise and SpO₂ will drop if activity is not tolerated.  
**Evaluation** Are vital signs and SpO₂ stable?

**Intervention** Allow patient to rest between activities. Bedrest may be needed during acute dyspnea.  
**Rationale** Even talking or eating can be exhausting to a patient who is dyspneic.  
**Evaluation** Is patient able to catch his or her breath between activities?

**Intervention** Obtain bedside commode, shower chair, handheld showerhead, if needed.  
**Rationale** Assistive devices can help the patient conserve energy.  
**Evaluation** Do assistive devices allow patient more independence?

**Intervention** Obtain portable oxygen if patient is able to ambulate.  
**Rationale** Portable oxygen may enable the patient to ambulate and prevent deconditioning.  
**Evaluation** Is patient able to ambulate and maintain SpO₂ within normal limits with portable oxygen?

**Intervention** Allow uninterrupted rest at night as much as possible.  
**Rationale** Lack of sleep can contribute to activity intolerance.  
**Evaluation** Is patient able to sleep uninterrupted? Can interferences be delayed until morning?

**Intervention** Slowly increase activity as able.  
**Rationale** Increasing activity helps maintain muscle tone and endurance.  
**Evaluation** Is patient able to increase a little each day? Is this a realistic goal for patient?

**Intervention** Refer patient with chronic lung disease to a pulmonary rehabilitation program.  
**Rationale** Pulmonary rehabilitation programs can help patient increase exercise tolerance.  
**Evaluation** Is patient willing to participate in a rehabilitation program?

---

**CRITICAL THINKING**

**Mr. Woo**

Mr. Woo is being tested for tuberculosis. You check his skin tests and find that the PPD test in his left forearm is negative, with no redness or induration. You also find that the *Candida* test in his right forearm is negative, with no redness or induration.

1. How do you document these results?
2. How do you interpret them?

*Suggested answers are at the end of the chapter.*
Nursing Care of Patients With Lower Respiratory Tract Disorders

Chapter 31

Nursing Process for the Patient With a Lower Respiratory Tract Infection

Priority nursing diagnoses and interventions for patients with lower respiratory infections are presented in the "Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder."

Restrictive Disorders

Restrictive disorders are those problems that limit the ability of the patient to expand his or her lungs and, therefore, inhale air. Restrictive disorders can be intrinsic, involving lung tissue (such as pulmonary fibrosis), or extrinsic, involving structures outside the lungs (such as pleural effusion). Restrictive disorders covered below include pleurisy, pleural effusion, empyema, pulmonary fibrosis, and atelectasis.

Pleurisy (Pleuritis)

Pathophysiology

Recall that the visceral and parietal pleurae are the membranes that surround the lungs. Between these membranes is a small amount of serous fluid that prevents friction as the pleurae slide over each other during inhalation and exhalation. If the membranes become inflamed for any reason, they do not slide as easily. Instead of sliding, one membrane may “catch” on the other, causing it to stretch as the patient attempts to take a breath. This causes the characteristic sharp pain on inspiration. The irritation causes an increase in the formation of pleural fluid, which in turn reduces friction and decreases pain.

Etiology

Pleurisy is usually related to another underlying respiratory disorder, such as pneumonia, tuberculosis, a tumor, or trauma. Nonrespiratory disorders such as pancreatitis or certain autoimmune disorders can also result in pleurisy.

Signs and Symptoms

Pleurisy causes a sharp pain in the chest on inspiration. Pain also occurs during coughing or sneezing. Breathing may be shallow and rapid because deep breathing increases pain. The patient may also exhibit fever, chills, and an elevated white blood cell (WBC) count if the cause is infectious. A pleural friction rub is heard on auscultation.

Complications

As pleural membranes become more inflamed, serous fluid production increases, which may result in pleural effusion (see next section). If pleuritic pain is not controlled, patients have difficulty breathing deeply and coughing, which may lead to atelectasis. If infection goes untreated, empyema can result.

Diagnostic Tests

Diagnosis is based on signs and symptoms, including auscultation of a pleural friction rub. A chest x-ray examination or ultrasound and complete blood cell count (CBC) may be done. FVC (forced vital capacity) is reduced more than FEV₁ (forced expiratory volume in 1 second) because expansion is limited by the restrictive disorder; airways and FEV₁ may be normal. Additional testing is done to determine the underlying cause.

Therapeutic Measures

Treatment is aimed at correcting the underlying cause. Nonsteroidal anti-inflammatory drugs (NSAIDs) or opioids are given to control pain and facilitate deep breathing and coughing. The physician may perform a nerve block by injecting anesthetic near the intercostal nerves to block pain transmission. Patients may also experience some pain relief when lying on their affected side.

Pleural Effusion

Pathophysiology

When excess fluid collects in the pleural space, it is called a pleural effusion. Fluid normally enters the pleural space from surrounding capillaries and is reabsorbed by the lymphatic system. When a pathological condition causes an increase in fluid production or inadequate reabsorption of fluid, excess fluid collects. A normal amount of pleural fluid around each lung is 1 to 15 mL. More than 25 mL of fluid is considered abnormal; in pleural effusion, as much as several liters of fluid can collect at one time. The effusion can be either transudative, forming a watery fluid from the capillaries, or exudative, with fluid containing WBCs and protein from an inflammatory or infectious process.

Etiology

Like pleurisy, pleural effusion is generally caused by another lung disorder. It is a symptom rather than a disease. Transudative effusions may result from heart failure, liver disorders, or kidney disorders. Exudative effusions more commonly occur with lung cancer, infection, or inflammation.

Signs and Symptoms

Symptoms depend on the amount of fluid in the pleural space. The patient may or may not experience pleuritic pain. Increasing shortness of breath occurs because of the decreasing space for lung expansion. Cough and tachypnea may be present. A dull sound is heard when the affected area is percussed. Lung sounds are decreased or absent over the effusion, and a friction rub may be auscultated.

Diagnostic Tests

A chest x-ray examination is done to determine whether pleural effusion is present. If a thoracentesis is done, fluid samples are sent to the laboratory for culture and sensitivity and cytological examination. Further tests are done to determine the cause of the effusion.
**Pulmonary Fibrosis**

**Pathophysiology**

Pulmonary fibrosis (PF), sometimes called interstitial lung disease, is a group of disorders that cause scarring and fibrosis of lung tissue. PF may evolve from injury to the alveoli, causing chronic inflammation; inflamed tissues are gradually replaced by fibrous connective tissue. Alveoli become thick and scarred, and gas exchange becomes difficult.

**Etiology**

Various factors are linked with pulmonary fibrosis, including heredity, exposure to certain viral illnesses, wood and metal dust exposure, medications, radiation therapy, and smoking. It may also be associated with some autoimmune disorders such as lupus erythematosus or rheumatoid arthritis. Chronic GERD may play a role. Often PF is called idiopathic PF because no specific cause can be found.

**Signs and Symptoms**

Patients with PF experience progressive shortness of breath. Inspiratory crackles and chronic cough are present. Some experience flulike symptoms. Fatigue is common, and clubbing of fingers may be present. Patients usually follow a downhill course.

**Diagnostic Tests**

A chest x-ray may show lung infiltrates. A CT scan may be done. Spirometry is done to verify that the condition is restrictive. ABGs may show reduced PaO₂. A bronchoscopy and lung biopsy can help rule out other causes of the patient’s symptoms and can show inflammation and fibrosis. A blood test (ANA titer) may show whether an autoimmune process is involved.

**Therapeutic Measures**

Glucocorticoids (steroids) are used to reduce inflammation. Drugs to suppress the immune system may reduce autoimmune activity. Patients should be encouraged to stop smoking and to avoid secondhand smoke. Oxygen is used if needed to maintain oxygenation. Patients should receive flu and pneumococcal vaccines. Younger patients may be considered for a lung transplant. Pulmonary rehabilitation helps patients maintain optimum activity tolerance.

**Atelectasis**

Atelectasis is the collapse of alveoli. It most commonly occurs in postsurgical patients who do not cough and deep breathe effectively, although it can be caused by anything that causes hypoventilation. Areas of the lungs that are not well aerated become plugged with mucus, which prevents inflation of alveoli. As a result, alveoli collapse. Compression of lung tissue from effusion or a tumor can also cause atelectasis. The focus of nursing care is on prevention. Patients should be taught the importance of coughing and deep breathing, or use of an incentive spirometer whenever the risk for hypoventilation is present. Frequent position changes and ambulation are also helpful.

**NURSING PROCESS FOR THE PATIENT WITH A RESTRICTIVE DISORDER**

**Data Collection**

Perform a routine respiratory assessment. Monitor lung sounds for friction rub or decreasing breath sounds in any of the lobes. Assess pain level and vital signs. Be vigilant for an increase in dyspnea, tachypnea, changes in vital signs or pulse oximetry, or an increased white blood cell count or temperature.

**Nursing Diagnoses, Planning, and Implementation**

Priority nursing diagnoses are similar to those for other respiratory disorders and are addressed in the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder.” In addition, it is essential to address pain (see below), because pain can prevent the patient from breathing effectively.

**Risk for Ineffective Breathing Pattern related to acute pain**

**EXPECTED OUTCOME:** The patient will be comfortable enough to breathe deeply and cough effectively and will have a respiratory rate of 12 to 20 per minute.

- Monitor respiratory rate and depth and pain location and level. Some types of pain can cause shallow respirations, especially pleuritic pain.
- Position patient for comfort. Sometimes laying on the affected side for short periods will help reduce chest wall movement and pain.
Administer pain medication as ordered, preferably around the clock, to prevent pain from becoming severe. Pain must be controlled so the patient can breathe deeply and prevent further complications. NSAIDs or acetaminophen are usually tried first because they will not suppress cough and respirations.

If opioids are required to control pain, carefully monitor respirations and cough. Opioids can suppress respirations and cough, which can further complicate the underlying disorder.

Teach patient the importance of effective deep breathing and coughing (see Chapter 29). This can help prevent further complications. If opioids have suppressed cough reflex, patient will need to purposefully deep breath and cough.

Request an order for an incentive spirometer. Incentive spirometry can help encourage the patient to breathe deeply.

**Evaluation**

If interventions have been effective, the patient should report a decrease in dyspnea and anxiety. Pain will be controlled so that the patient is able to take deep breaths and cough effectively. Breath sounds will be clear and equal bilaterally, and the patient will be free of signs and symptoms of infection.

---

**OBSTRUCTIVE DISORDERS**

Obstructive disorders are characterized by air trapping and difficulty getting air out of the lungs. Obstructive disorders covered in this chapter include COPD, emphysema, chronic bronchitis, asthma, and cystic fibrosis.

**Chronic Obstructive Pulmonary Disease/Chronic Airflow Limitation**

According to the National Heart, Lung, and Blood Institute (NHLBI), chronic obstructive pulmonary disease (COPD) is the third leading cause of death in the United States. More than 12 million adults have been diagnosed with COPD, and another 12 million likely have it but have not yet been diagnosed. COPD kills more than 120,000 Americans each year (NHLBI, n.d.). In the past, it was more common in men, but the incidence in women is rising because more women now smoke.

**Pathophysiology**

COPD is a group of pulmonary disorders characterized by difficulty exhaling because of airways that are narrowed or blocked by inflammation and mucus and because the loss of elastic fibers causes an increase in compliance. More effort is required for the weakened alveoli to push air out through obstructed airways (Fig. 31.3). Emphysema, chronic bronchitis, and asthma are disorders that limit airflow. A patient with COPD may have some degree of both emphysema and chronic bronchitis, although usually bronchitis is the dominant disorder. Asthma may also be present, but it differs somewhat because the airway limitation in asthma is usually reversible. A patient with unremitting asthma is treated as having COPD. Airflow limitation in emphysema and bronchitis is progressive and minimally reversible (Fig. 31.4).
COPD may also be referred to as chronic airflow limitation (CAL) or chronic obstructive lung disease (COLD). COPD develops slowly and may be present for many years before symptoms become evident, and it may be advanced by the time the patient seeks treatment. It is characterized by periods of relative stability and exacerbations (acute worsening of symptoms), which may be triggered by respiratory infection or other stressors. (See Table 31.3 for a COPD summary.)

**LEARNING TIP**

Restrictive disorders cause difficulty with inhalation or air entering the lungs. Obstructive disorders are associated with difficulty exhaling or getting air out.

**CHRONIC BRONCHITIS PATHOPHYSIOLOGY.** Chronic bronchitis is similar to acute bronchitis, with symptoms occurring for at least 3 months of the year for 2 consecutive years. Patients may have multiple exacerbations, each lasting 2 weeks or more. The bronchial tree becomes inflamed from inhaled irritants, and impaired ciliary function reduces the ability to remove the irritants. The mucus-producing glands in the airways become hypertrophied, producing excessive thick, tenacious mucus, which obstructs airways and traps air (Fig. 31.5A). These changes lead to chronic low-grade infection.

**EMPHYSEMA PATHOPHYSIOLOGY.** Emphysema affects the respiratory bronchioles and alveoli distal to the terminal bronchioles, causing destruction of the alveolar walls and loss of elastic recoil (see Fig. 31.5C). This also causes damage to adjacent pulmonary capillaries. Because of the loss of elastic recoil, passive exhalation is impaired and air is trapped in the alveoli. The combination of damaged alveoli and capillaries causes reduced surface area for gas exchange. Emphysema can occur primarily in the respiratory bronchioles (centrilobular emphysema), with delayed alveolar damage, or in the respiratory bronchioles and alveoli (panlobular emphysema; Fig. 31.6).

**Etiology**

Smoking is the single most important risk factor for COPD. Other factors include passive (secondhand and possibly third-hand) smoking, indoor and outdoor air pollution, and exposure to industrial chemicals. Some familial predisposition to chronic bronchitis has been demonstrated. A small number of individuals have an inherited deficiency of the enzyme α₁-antitrypsin (α₁AT), which causes a predisposition to the development of emphysema. Patients with this inherited tendency who also smoke have a very high risk of developing the disease. Children of smoking parents are at higher risk because of smoke exposure.

**Prevention**

Prevention is important because no cure for COPD is currently available. Avoidance of smoking and other inhaled irritants is vital, especially in those individuals with parents or siblings with COPD. According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD; 2013) guidelines, “Smoking cessation is the intervention with the greatest capacity to influence the natural history of COPD.”

**NURSING CARE TIP**

This is a self-care tip. If you are a smoker, now is a good time to quit. COPD is deadly. Check Chapter 29 for ways to quit smoking. Or visit www.tobaccofreenurses.org. You CAN do it! Good luck!
FIGURE 31.5 (A) Chronic bronchitis. Note inflamed airways and excessive mucus. (B) Asthma. Note narrowed bronchial tubes and swollen mucous membranes. (C) Emphysema. Note distended respiratory bronchioles and alveoli.

FIGURE 31.6 Types of emphysema. (A) Normal lungs. (B) Centrilobular emphysema. (C) Panlobular emphysema.
COPD is classified according to spirometry results and symptoms into four grades, from grade 1 (mild airflow limitation) to 4 (very severe airflow limitation).

**Therapeutic Measures**

The goals of COPD treatment, according to the GOLD guidelines, are as follows:

- Relieve symptoms.
- Improve exercise tolerance.
- Improve health status.
- Prevent disease progression.
- Prevent and treat exacerbations.
- Reduce mortality (GOLD, 2013).

In addition, cessation of cigarette smoking should be included as a goal throughout any management program.

**SMOKING CESSATION.** Even late in the disease process, stopping smoking can slow disease progression and prolong life. Exposure to other respiratory contaminants should also be minimized. Hair spray, other household aerosols, and body powder should be avoided. Figure 31.7 shows the benefit of smoking cessation and impact on the length of time to disability and death. “Patient Perspective” is a personal account from one woman who understood too late the importance of smoking cessation.

**OXYGEN.** Oxygen therapy is usually delayed until grade 4 disease, and then is used to keep SpO2 at or above 90%. It

---

**Patient Perspective**

**Sarah**

At age 17, I started the habit that would change my life. I started to smoke.

At first it was just a few cigarettes, but as time passed I smoked more and more until I reached two packs a day. This habit continued for 42 years. I disregarded all the warnings about what could happen. I was sure this would never happen to me.

Now at age 75, I must do three breathing treatments a day and carry an inhaler with me at all times. I have a cough that cannot be controlled. I can no longer ride a bike with my grandchildren, play badminton, or even bowl. My lungs won’t let me. Going shopping is no longer fun—it’s a chore. I have to walk slowly or I can’t breathe.

All the things I enjoyed most I’ve given up because for 42 years I was a slave to cigarettes. If any of you smoke, stop now. Smell the coffee and roses without coughing.
usually is ordered at a flow rate of 1 to 2 L/min. Higher flow rates may suppress the hypoxic drive in patients who are chronic CO₂ retainers, although this is uncommon. Higher flow rates may be used during acute exacerbations in a monitored setting. Patients with chronic oxygen saturation levels of 88% or less should be placed on oxygen at home.

**MEDICATIONS.** Medications commonly used include adrenergic and anticholinergic metered-dose inhalers or nebulized mist treatments to open airways, corticosteroid inhalers to control inflammation, and intermittently when needed, antibiotics. Much focus is now placed on a combination of long-acting adrenergic agents and corticosteroids (Advair, Symbicort) and a new long-acting anticholinergic agent (tiotropium [Spiriva]), all of which may reduce exacerbations and prolong survival. Antitussive agents should be avoided in patients with COPD because they need to be able to cough up secretions.

Oral theophylline bronchodilators are sometimes used but have significant side effects so are avoided if possible. Oral or IV corticosteroids are used for acute exacerbations. Replacement of α1AT may be used in emphysema patients who are deficient. See Table 31.4 for a more detailed list of medications used in the treatment of COPD.

Patients with COPD should also be assessed for depression. Depression is common with chronic illness and often

goes undiagnosed. Patients may not report feeling depressed but may experience more physical symptoms. Antidepressant medications, if indicated, can increase quality of life for COPD patients.

Morphine or other opioids may be effective in reducing acute dyspnea and anxiety. They are reserved for end-stage disease.

**SUPPORTIVE CARE.** A pneumococcal vaccination and yearly influenza vaccinations are recommended to reduce the risk of respiratory infection. Avoidance of crowds and exposure to people with respiratory infections is advised.

Good hydration and a cool mist humidifier help keep secretions loose. Chest physiotherapy may be used to help the patient remove excessive secretions. A dietitian consultation is helpful for the patient who is unable to maintain a desirable weight. Typically a high-protein, high-fat, low-carbohydrate diet is prescribed. Breathing exercises help improve oxygenation and reduce anxiety (see Chapter 29).

</table>

*Note: This table is an overview. A drug guide should be consulted for complete administration guidelines. MDI = metered-dose inhaler.*
**REHABILITATION.** Pulmonary rehabilitation programs can help patients increase exercise tolerance and maintain a sense of well-being (Fig. 31.8). Patients exercise in a monitored environment and benefit from the support of other patients with similar problems. Some groups of pulmonary rehabilitation patients have even formed harmonica clubs! Playing their harmonicas mimics pursed-lip breathing and may strengthen the diaphragm, the major muscle of breathing.

**SURGERY.** Surgical removal of emphysematous lung tissue (called lung volume reduction surgery, or LVRS) increases the space available for good lung tissue to expand, reducing dyspnea and increasing exercise tolerance. This is a high-risk procedure, but it has allowed some patients to return to a more normal activity level and improved quality of life. Surgery may also be performed to remove blebs in an attempt to prevent pneumothorax. Lung transplant may be an option in select patients.

**ENDOBRONCHIAL VALVE.** A newer treatment is similar to lung reduction surgery, but without the surgery. It is placement of a tiny one-way valve via bronchoscopy into an area of emphysematous lung, which causes the diseased area to collapse. This then allows the healthy lung tissue more space to expand. It has been shown to increase FEV$_1$ and exercise tolerance. Research is ongoing on this intervention.

**MECHANICAL VENTILATION.** If arterial blood gases worsen despite treatment, intubation and mechanical ventilation may be considered, depending on the patient’s advance directive. Unfortunately, mechanical ventilation will not make a patient’s disease better, and weaning may be difficult or impossible once it is initiated. Use of noninvasive positive-pressure ventilation (NIPPV; see Chapter 29) may be a good alternative for many patients.

**END-OF-LIFE PLANNING.** It is important to assess whether the patient has a living will or durable power of attorney for health care (DPOA; see Chapter 17). COPD is a progressive disease, and patients can increase the quality of their life and death by making decisions in advance. Patients should make decisions about whether they would want to be intubated and mechanically ventilated, or have cardiopulmonary resuscitation (CPR) in event of a cardiac arrest. CPR is rarely successful in a patient with end-stage disease. Patients should be made aware of palliative care options and assured that they will be kept as comfortable as possible.

Research is ongoing to determine which treatments will alter long-term outcomes of the disease. Check the American Lung Association website for more information at www.lungusa.org.

**Nursing Process for the Patient With COPD**

See “Nursing Process for the Patient With an Obstructive Disorder” and the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder.” Priority nursing diagnoses for the patient with COPD include Impaired Gas Exchange, Ineffective Airway Clearance, and Activity Intolerance.

**Asthma**

The incidence of asthma is on the rise. Nearly 19 million adults and 7.1 million children in the United States have asthma (CDC, 2013b). It accounts for 3.1 million urgent care and emergency department visits each year. Asthma is more prevalent in African Americans than in whites. Asthma deaths are more common in lower socioeconomic groups, possibly because of poor access to treatment or less compliance with treatment. With careful monitoring and treatment, however, patients with asthma can manage their symptoms and lead normal lives.

**Pathophysiology**

Asthma is characterized by chronic inflammation and edema of the mucosal lining of the airways and hyperresponsiveness of the bronchial smooth muscles (bronchospasm). This causes narrowed airways and air trapping, which is why it is considered an obstructive disorder (see Fig. 31.5B). Inflammation occurs in part because things that trigger asthma (asthma triggers) cause release of inflammatory substances such as histamine and leukotrienes. Symptoms are intermittent and generally reversible, with periods of normal airway function. Some people develop permanent changes in their airways, called remodeling; this leads to a progressive loss of lung function.

**Figure 31.8**

Patients build exercise tolerance in pulmonary rehabilitation programs. Note therapist monitoring oxygen saturation.
About 50% of patients develop the disorder in childhood, and some outgrow it. However, a significant number develop symptoms again later in life. Children with asthma should be counseled that smoking can increase the risk of recurrence in adulthood. Asthma may also complicate chronic bronchitis or emphysema.

**Etiology**
The tendency to develop asthma is inherited. The most common predisposing factor is the genetic tendency to be allergic to airborne allergens such as pollen or molds. Viral respiratory infections are also a contributing factor to asthma diagnosis and exacerbation. Tobacco smoke, air pollution, early use of antibiotics, and sensitization to house-dust mites and cockroaches have also been linked to asthma development.

**Asthma Triggers**
Once asthma develops, a number of triggers can cause an acute attack. Exposure to allergens such as dust mites, cockroaches, cat and dog dander, or pollen can trigger an attack. Other possible triggers include emotional upset, exercise, medications (aspirin, beta blockers), and GERD. GERD can trigger an attack because stomach acid can reflux into the esophagus and then be aspirated, causing an exacerbation of symptoms. This occurs especially at night. GERD and its treatment are discussed in Chapter 33.

**Prevention**
Although asthma cannot be prevented at this time, research is ongoing to determine factors associated with its development. Some studies have suggested that the presence of older siblings in the home, early exposure to daycare, certain infections, or a rural environment may be protective against asthma development in childhood. Appropriate control of childhood asthma may prevent more serious asthma in later years. Avoidance of smoking may reduce the risk of recurrence of asthma that started in childhood. To prevent acute attacks, it is important that the patient identify triggers of asthma symptoms and avoid them whenever possible. Monitoring of symptoms and compliance with prophylactic and maintenance therapy is also important.

**Signs and Symptoms**
Asthma symptoms are intermittent and are often referred to as attacks, which may last from minutes to days. Patients report chest tightness, dyspnea, coughing, and difficulty moving air in and out of the lungs. Symptoms are often worse at night. Some patients experience coughing but no wheezing. Once initial symptoms are controlled, airways may remain hyper-sensitive and prone to asthma symptoms for many weeks.

On examination, you will note an increased respiratory rate as the patient attempts to compensate for narrowed airways. Inspiratory and expiratory wheezing is heard because of turbulent airflow through swollen airways with thick secretions; wheezing may sometimes be audible even without a stethoscope. Air is trapped in the lungs, and expiration is prolonged. A cough is common and may produce thick, clear sputum. Use of accessory muscles to breathe is a sign that the attack is severe and warrants immediate attention.

Be aware that an absence of audible wheezing may not signal improvement but rather may be an ominous sign that the patient is not moving enough air to make any sound. If wheezing is not heard, use of accessory muscles and peak expiratory flow rate values must be carefully evaluated. Once treatment begins to open the airways, wheezing may become audible.

Asthma is classified according to frequency of symptoms (Table 31.5).

<table>
<thead>
<tr>
<th>Classification</th>
<th>Symptoms</th>
<th>SABA Use</th>

<tr>
<td>Moderate persistent</td>
<td>Asthma symptoms every day; nighttime awakenings more</td>
<td>SABA use daily.</td>
<td>Some activity limitation.</td>
<td>FEV&lt;sub&gt;1&lt;/sub&gt; greater than 60% but less than 80% predicted.</td>
</tr>
</tbody>
</table>
Complications

**Status asthmaticus** occurs if bronchospasm is not controlled and symptoms are prolonged. As the patient increases the respiratory rate to compensate for narrowed airways, a lot of carbon dioxide is blown off and respiratory alkalosis occurs. If the attack is not resolved and the patient begins to tire, the patient will no longer be able to compensate, and $\mathrm{PaCO}_2$ will rise, resulting in respiratory acidosis. This can lead to respiratory failure and death if untreated.

**Diagnostic Tests**

Diagnosis is based on the patient's report of symptoms, physical examination, and spirometry results. Peak expiratory flow rate and $\mathrm{FEV}_1$ are reduced, especially during symptomatic periods. Asthma can be differentiated from COPD during spirometry testing by administering an adrenergic agonist (such as albuterol) and then retesting. Asthma symptoms can generally be reversed with the medication, but COPD cannot. Allergy skin testing and increased serum immunoglobulin E and eosinophil levels indicate allergic involvement and may help determine appropriate treatment. ABGs may be evaluated during an acute severe attack.

On a long-term basis, asthma control can be evaluated using $\mathrm{FEV}_1$, or peak flow measurements, frequency and severity of exacerbations and nighttime awakenings, and frequency of short-acting beta-agonist use.

**Therapeutic Measures**

Patients must learn to manage asthma at home. If they can monitor and manage their symptoms, acute episodes and hospitalizations can be avoided.

**SELF-MONITORING.** All patients benefit from learning to monitor their asthma symptoms and make treatment decisions accordingly. This can be done by carefully monitoring symptoms or by monitoring peak expiratory flow rate (PEFR; Fig. 31.9). PEFR is a measurement, in liters per minute, of the amount of air a patient can blow into a peak flow meter from fully inflated lungs. The patient determines his or her baseline PEFR during symptom-free times. Readings can be charted to keep track of progress (Fig. 31.10). If symptoms worsen or PEFR begins to fall below the patient's baseline, treatment that has been predetermined with the HCP should be initiated (Fig. 31.11). If treatment does not improve PEFR to the expected degree, the patient is advised to go to the emergency room. PEFR results may indicate the onset of asthma before the patient experiences any obvious symptoms.

**AVOIDANCE OF TRIGGERS.** The patient is instructed to identify and avoid asthma triggers. If triggers cannot be avoided, the patient can use bronchodilator or mast cell stabilizer inhalers as prescribed before exercise. Inhalers can be especially useful before exercise. Recent studies have shown that a high-salt diet may worsen exercise-induced airway inflammation. Animal dander and foods that cause symptoms are best avoided when possible. Eliminating carpets and curtains in bedrooms, using vinyl mattress and pillow covers, and installing a portable or central air filter can reduce dust mite exposure. Maintenance of indoor humidity between 40% and 50% can reduce mold growth. If cold air triggers symptoms, the patient should keep the nose and mouth covered when outside in cold weather. Smoking and exposure to second-hand smoke are strongly discouraged.
Aspirin and NSAIDs can cause asthma symptoms in some individuals. Beta-blocking medications (propranolol, metoprolol), used commonly for hypertension, block beta receptors in the lungs, preventing the sympathetic nervous system from promoting bronchodilation. These drugs should be avoided if they make symptoms worse.

**MEDICATIONS.** Medications for asthma treatment may be used intermittently or continuously, depending on the persistence of symptoms. Inhaled medications are preferred because they cause fewer adverse effects than oral or injected medications. See Table 31.4 for a summary of medications used in the treatment of lower respiratory disorders.

For patients with intermittent symptoms, short-acting beta agonists (SABAs) such as albuterol are used to dilate bronchioles. They are administered via metered-dose inhaler when symptoms occur and are often called rescue inhalers. They can also be administered preventively before exercise or other events that trigger asthma.

If the patient needs to use a rescue inhaler more than two times a week for symptoms, maintenance medications to prevent symptoms will likely be started. Inhaled corticosteroids such as fluticasone or budesonide are generally added first to control inflammation. Instruct the patient that corticosteroids must be used regularly to prevent symptoms and that they do not provide immediate symptom relief during an acute attack.

Long-acting beta-agonist bronchodilators (LABAs) such as salmeterol (Serevent) or formoterol (Foradil) can also help prevent symptoms by keeping airways dilated for up to 12 hours or more. Research in recent years, however, has questioned their safety, and they are no longer recommended to be used alone. If they are used, they should be used in combination with inhaled corticosteroids (Advair, Symbicort).

Mast cell stabilizers (cromolyn sodium, nedocromil) may help prevent symptoms but are often not useful. Some patients use mast cell stabilizers 10 to 15 minutes before exposure to allergens or exercise to reduce symptoms.

If inhaled medications do not control symptoms or if the patient has nocturnal symptoms, oral antileukotrienes may be added; theophylline bronchodilators are generally used as a last resort because of their many side effects. Immunotherapy (allergy shots) may be used for some patients with allergic asthma.

An acute asthma attack may be treated with an inhaled (metered dose inhaler or nebulized mist treatment) or, rarely, IV aminophylline. IV or oral corticosteroids (methylprednisolone, prednisone) are potent anti-inflammatory agents that are useful in an acute episode but are avoided for long-term therapy if possible because of their cushingoid side effects. (See the section on Cushing’s syndrome in Chapter 39.) Corticosteroids must be tapered before discontinuing to prevent withdrawal symptoms. (See the section on addisonian crisis in Chapter 39.)
It is important for patients to understand the difference between long-acting maintenance medications and rescue medications and to use them appropriately. Oxygen is generally not necessary because many patients hyperventilate during an acute attack. If the attack is prolonged and the patient becomes cyanotic or PaO₂ levels begin to fall, oxygen therapy will be used.

**NURSING CARE TIP**

Instruct the patient to contact the HCP if using more than two adrenergic metered dose inhaler canisters per month. This has been associated with an increased risk of death.

**Cystic Fibrosis**

In the past, cystic fibrosis (CF) was thought to be just a childhood disease because most affected children did not survive past puberty. However, with new treatments, patients with CF are living longer and more productive lives. Some CF patients now marry, have careers, and live well into their 30s.

**Pathophysiology**

CF is a disorder of the exocrine glands that affects primarily the lungs, GI tract, and sweat glands. The disease varies in severity; some patients have no GI involvement. Abnormal sodium and chloride transport across cell membranes, causing thick, tenacious secretions, is responsible for many of the characteristic symptoms. Thick, sticky respiratory secretions that are difficult to remove cause airway obstruction, resulting in air trapping and frequent respiratory infections.

**Nursing Process for the Patient With Asthma**

See the “Nursing Process for the Patient With an Obstructive Disorder” section, following the section on cystic fibrosis in this chapter. Primary nursing diagnoses include *Impaired Gas Exchange, Ineffective Airway Clearance,* and *Anxiety.* See Table 31.6 for an asthma summary.
Similar abnormalities in the pancreas cause blocked ducts and retained digestive enzymes. These retained enzymes digest and destroy the exocrine pancreas. The absence of digestive enzymes in the intestines causes malabsorption of essential nutrients; frequent foul-smelling, fatty stools; and excess flatus. Patients with CF secrete sweat that is high in sodium and chloride because these electrolytes are not reabsorbed as they pass through the sweat ducts.

**Etiology**

CF is a genetic disorder. Both parents must be carriers of the defective gene for CF to be present in a child. Patients with CF who marry are counseled on the risk of offspring having the disease.

**Signs and Symptoms**

Symptoms usually first appear in infancy or childhood, although a few individuals are not diagnosed until adulthood. Respiratory symptoms are often the first visible manifestation of the disease and range from chronic sinusitis to production of thick, tenacious sputum. Patients with CF are at risk for frequent respiratory infections, with coughing and purulent sputum. Finger clubbing is common. Late in the disease, hemoptysis may occur related to damaged blood vessels within the lungs. Over time, bouts of infection become more frequent, with eventual loss of lung function and respiratory failure. Antibiotic-resistant infections are a threat to life in these individuals.

Frequent foul-smelling stools result from the lack of enzymes in the small intestine. Inability to absorb fat-soluble vitamins and poor appetite due to respiratory disease result in malnutrition. Bowel obstruction, cirrhosis, cholecystitis, and cholelithiasis are associated findings. Chronic disease causes delayed sexual maturation in both males and females, and infertility is common.

**Complications**

Patients with CF are at risk for a variety of complications, including bronchiectasis, pneumothorax, cor pulmonale, and respiratory failure. Bowel obstructions can occur as a result of thick mucus binding with poorly digested fecal matter. Diabetes from pancreatic islet cell involvement may be present late in the disease. Death is usually the result of pulmonary complications, especially antibiotic-resistant infection.

**Diagnostic Tests**

Because so many different gene mutations can occur in CF, genetic testing may be used to confirm a suspicion of CF but not for screening. Testing can also help prospective parents determine if they are carriers. The standard diagnostic test is the sweat chloride test. If respiratory symptoms are accompanied by excessive amounts of sodium chloride in sweat, CF is diagnosed. You may recall public health campaigns that advise parents to kiss their babies and report any salty taste to their HCPs. Genetic testing can be done on blood samples of newborns who have respiratory symptoms. Chest x-ray and spirometry also may be done.

**Therapeutic Measures**

Because there is no cure for CF, treatment is aimed at controlling infection and relieving symptoms. Removal of thick sputum is promoted with hydration, use of a vibratory PEP device, chest physiotherapy, or high-frequency chest wall oscillation vest (see Chapter 29) up to four times a day. Regular exercise also helps mobilize secretions; pulmonary rehabilitation may be beneficial. All forms of smoke should be avoided. A hot shower may be an easy occasional alternative to loosen secretions. Nebulized mist treatments using normal or hypertonic saline or mucolytic medications may be used before chest physiotherapy. An inhaled medication called dornase alpha (Pulmozyme) is an enzyme that breaks up and loosens mucous; it has been shown to reduce lung infections and improve lung function. Bronchitol, mentioned earlier in the section on bronchiectasis, is also being studied for CF. Inhaled beta-agonist bronchodilators help keep airways open. Ivacaftor (Kalydeco) is a new oral medication that is being studied to improve the function of a protein that is defective in patients with CF. It is the first drug that will target the underlying cause of CF rather than treat symptoms. High doses of ibuprofen (Motrin) may slow lung deterioration. Breathing exercises, incentive spirometry, and effective coughing techniques such as autogenic drainage (see Chapter 29) are also helpful. Lung transplant is a potentially promising treatment.

Prevention of infection is vital to slowing progression of lung damage. Patients should receive a yearly flu vaccination. Antibiotics must be administered as soon as signs of infection occur. Prophylactic antibiotic therapy may be
used. Some patients use inhaled antibiotics for chronic infection; others are on home IV antibiotic therapy. Antibiotic-resistant infections are a deadly threat to the patient with CF. Patients must be vigilant in avoiding others with infections.

Pancreatic enzyme replacement (Pancrease, Viokase) helps reduce symptoms related to malabsorption and improve nutritional status. An increase in calorie requirements necessitates a high-calorie, nutrient-dense diet. For more information, visit the Cystic Fibrosis Foundation at www.cff.org.

Nursing Process for the Patient With Cystic Fibrosis

See the “Nursing Process for the Patient With an Obstructive Disorder” section next. Also, be sure to remember the special needs of the adolescent patient with this chronic, debilitating disease. Not only are normal physical growth and development delayed, but psychosocial development is also affected by repeated hospitalizations and the necessity of routine daily medication and treatments.

CRITICAL THINKING

Mr. Jenkins

Mr. Jenkins is a 36-year-old accountant with bronchiectasis secondary to cystic fibrosis. You enter his room during an episode of uncontrollable coughing and offer him support. You observe his sputum as you dispose of it—a whole Styrofoam coffee cup full of thick, bright yellow sputum; the smell makes you nauseated. Even after coughing, his lungs sound congested from retained secretions. You offer him mouth care before you leave his room.

1. What questions can you ask Mr. Jenkins to assess his cough?
2. What nursing diagnosis is most appropriate for Mr. Jenkins?
3. What nursing care can you provide to enhance secretion removal?
4. How would you document this episode of coughing?
5. What other team members can you collaborate with to provide the best care for Mr. Jenkins?

Suggested answers are at the end of the chapter.

NURSING PROCESS FOR THE PATIENT WITH AN OBSTRUCTIVE DISORDER

Data Collection

Perform a complete respiratory assessment as presented in Chapter 29. Frequency of assessment is dictated by the severity of the patient’s condition. Note orientation and level of consciousness; poor gas exchange can cause confusion and lethargy. Assess respiratory rate and effort. Observe skin and mucous membranes for cyanosis. Auscultate lungs for adventitious sounds. Monitor cough and the color, viscosity, odor, and amount of sputum. Note exercise tolerance, and have patient report degree of dyspnea on a scale of 0 to 10. Monitor vital signs, oxygen saturation, and arterial blood gases if ordered. Careful documentation of findings allows you to be vigilant for trends in the patient’s progress.

Nursing Diagnoses, Planning, and Implementation

A number of nursing diagnoses are appropriate for the patient with an obstructive disorder. As always, choose diagnoses based on defining characteristics and the patient’s individual assessment findings.

Priority nursing diagnoses for most chronic respiratory patients include Impaired Gas Exchange, Ineffective Airway Clearance, Ineffective Breathing Pattern, and Activity Intolerance. Interventions for these diagnoses are presented in the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder.” Related diagnoses are discussed next.

Imbalanced Nutrition: Less Than Body Requirements related to poor appetite and increased calorie expenditure as evidenced by weight loss or low weight for height

Expected Outcome: The patient’s weight will be stable at desired weight for height.

• Monitor food intake and weekly weight. Regular monitoring can help identify nutrition problems before they are severe.
• If the patient is too dyspneic to eat, schedule rest periods and bronchodilator treatments before meals. Eating takes a lot of energy, and resting can help conserve energy before a meal. Bronchodilators can reduce dyspnea while eating.
• Create a pleasant eating environment. Unpleasant views or odors can spoil an appetite.
• Provide smaller, more frequent meals of the patient’s favorite foods. Eating a lot at one time can fill up the stomach and reduce room for lung expansion.
• Encourage family members to bring favorite foods from home for the hospitalized patient. A large tray of unappetizing food may be more than a patient can handle and may spoil the appetite. Be sure to note sodium or other restrictions; although the patient with end-stage disease may be allowed a more lenient diet, excess sodium can cause fluid retention and increase dyspnea.
• Consult a dietitian for liquid supplement recommendations. A specialized supplement such as Pulmocare provides less carbon dioxide than other supplements when metabolized and may be used for patients with chronic respiratory disease.
• See also “Nutrition Notes—Optimizing Nutrition in Patients With Respiratory Disease.”
Anxiety related to acute dyspnea as evidenced by statement of anxiety, tense appearance, tremors

**EXPECTED OUTCOME:** The patient will state that anxiety is controlled; appearance of tension and tremors will be absent. The patient will use techniques to control dyspnea and anxiety when they occur.

- Stay with a patient who is acutely dyspneic and anxious. *Feeling alone during episodes of dyspnea can increase anxiety.*
- Calmly remind the patient to breathe slowly in through the nose and out through pursed lips. *During acute episodes of dyspnea, the patient may forget that breathing exercises can help.*
- Teach relaxation exercises during times when anxiety is minimal, and remind the patient to use them during acute anxiety. *Relaxation exercises can help reduce muscle tension and distract the patient.*
- Administer antianxiety medications as ordered. *Medications can reduce anxiety but can also depress respirations, so should be used with caution.*
- Administer IV morphine (or contact RN to do so). *Morphine helps acute dyspnea and anxiety in patients with end-stage disease.*

**Evaluation**

If interventions have been effective, the patient will learn techniques to make breathing as comfortable as possible and will be able to cough up secretions and maintain a clear airway. He or she will be able to manage anxiety symptoms and complete ADLs or other desired activity without dyspnea. The patient’s intake should be adequate to maintain a stable weight. If any of the patient’s goals have not been met, the plan of care should be revised.

**Patient Education**

The patient must be aware of the contributing factors to the disease and eliminate them if at all possible. The patient who is a smoker should not simply be told to quit smoking; he or she should be referred to a smoking cessation program and be provided with medication, nicotine patches, or other resources and support as necessary to quit (see Chapter 29). Techniques for effective breathing and anxiety control should also be taught. A formal pulmonary rehabilitation program is an excellent resource for patient education.

---

**Nutrition Notes**

**Optimizing Nutrition in Patients With Respiratory Disease**

Malnutrition affects up to 60% of COPD patients and is associated with poor outcomes. Calorie requirements commonly are increased in patients with pulmonary disease. When caloric intake is inadequate, the body begins to break down muscle stores, including the respiratory and GI muscles, which only worsens the problem.

Causes of inadequate food intake can include the following:
- Anorexia
- Shortness of breath
- Fatigue (too tired to eat)
- Pressure from the GI tract impinging on the chest
- Medication side effects

Many patients with COPD have carbon dioxide retention and oxygen depletion. Because fat calories produce less carbon dioxide when metabolized than carbohydrate calories, diets with increased fat and decreased carbohydrate have been suggested, and special supplements for pulmonary patients have been designed and marketed. Energy needs may be 140% of normal and protein needs 150% of normal for maintenance. Nevertheless, it is important not to overfeed the patient. Excess intake can raise the demand for oxygen and the production of carbon dioxide beyond the patient’s capacity to manage them.

For the patient with inadequate intake, useful dietary strategies include the following:
- Offer small, frequent feedings of nutrient-dense foods by adding butter, peanut butter, margarine, mayonnaise, sauces, and gravies.
- Select foods that require little or no chewing: eggs, custards, puddings, soups with additional whole milk or powdered milk.
- Include sources of the following vitamins:
  - A (fortified milk, carrots) for healthy epithelial tissue
  - C (citrus fruit, peppers) to prevent infections.
- Discourage gas-producing foods to lessen abdominal pressure on the diaphragm.
- Offer oral nutritional supplements that have shown improved total intake, anthropometric measures, and grip strength in COPD clients (Collins, Stratton, & Elia, 2012).

Nutrition support also improves the likelihood of successful weaning in patients receiving mechanical ventilation.

PULMONARY VASCULAR DISORDERS

Pulmonary Embolism

Pathophysiology

An embolism is a foreign object that travels through the bloodstream. It may be a blood clot, air, or fat. A pulmonary embolism (PE), sometimes called a pulmonary thromboembolism (PTE), is usually a blood clot that has traveled into a pulmonary artery (Fig. 31.12). Resulting obstruction of blood flow causes a ventilation-perfusion mismatch, which in this case means that an area of the lung is well ventilated with air but has no blood flow, or perfusion. Because reduced or no blood supply is available to pick up the oxygen in the affected portion of the lung, it becomes pulmonary “dead space,” causing seriously impaired gas exchange.

Occasionally, damage occurs to a portion of the lung because of lack of oxygen. This is called lung infarction, and it is not common because oxygen is delivered to lung tissue not only from the pulmonary arteries but also via the bronchial arteries and the airways.

Etiology

Most pulmonary emboli originate in the deep veins of the lower extremities (deep venous thrombosis [DVT]). Some risk factors for DVT, and therefore PE, include surgical procedures done under general anesthesia, heart failure, fractures of the lower extremities, immobility, obesity, oral contraceptive use, smoking, and a previous history of DVT or PE. Prolonged immobility on airline flights is also a risk factor. Less common causes of PE include fat emboli from compound fractures, amniotic fluid embolism during labor and delivery, and air embolism from entry of air into the bloodstream.

Prevention

Prevention of thrombi in the deep veins of the legs is the most important factor in the prevention of a PE. Regular ambulation is advised if the patient is able. If a patient is at risk for DVT or PE, such as following surgery or during times of immobility, low-dose subcutaneous heparin or enoxaparin, or oral warfarin (Coumadin) may be used for anticoagulation. Intermittent compression stockings may also be used. If a DVT is diagnosed, prompt treatment is essential to prevent PE.

Signs and Symptoms

The most common symptom of PE is a sudden onset of dyspnea for no apparent reason. The patient may be gasping for breath and appear anxious. Tachycardia, tachypnea, cough, and pleuritic chest pain may be present. Auscultation may reveal crackles or a friction rub. If lung infarction has occurred, hemoptysis may also be present. Some patients have no symptoms at all. Be vigilant for the presence of risk factors and obtain immediate assistance if the cause of dyspnea might be PE. Death can occur if treatment is not fast and effective.

Complications

High blood pressure within the pulmonary circulation (pulmonary hypertension) may result from arterial occlusion and lead to right ventricular failure. This occurs because the right ventricle is unable to push blood into the occluded artery. As a result, the contraction becomes weak, cardiac output falls, and the patient becomes hypotensive.

Diagnostic Tests

A spiral CT scan with contrast dye is noninvasive and can diagnose PE quickly. If this is not available, a lung scan (ventilation-perfusion scan) is done to assess the degree of ventilation of lung tissue and the areas of blood perfusion. If an area is well ventilated but poorly perfused (i.e., a mismatch), PE is suspected.

and find him sitting on the bedside commode with a look of panic in his eyes. He is gasping for breath, his color is gray, and his respiratory rate is 36 per minute.

1. What do you do first? What assessment is appropriate? Whom can you call for assistance?
2. What can you teach Mr. Franklin to prevent an acute dyspneic episode in the future?
3. How will you document this episode?

Suggested answers are at the end of the chapter.

FIGURE 31.12 Pulmonary embolism.
A pulmonary angiogram is an invasive test that can outline the pulmonary vessels with a radiopaque dye injected via a cardiac catheter. It can show where blood flow is diminished or absent, suggesting an embolism. Chest x-ray examination, electrocardiogram (ECG), arterial blood gas analysis, or magnetic resonance imaging (MRI) may also be done. However, many of these show changes only in the presence of a very large embolism or infarction.

A D-dimer blood test can be helpful to rule out PE. Results can be obtained in less than an hour. D-dimer is a fibrin fragment that is found in the blood after any thrombus formation. It can be present in a number of disorders, but if it is negative, PE can be eliminated as a possible cause of the patient’s symptoms.

**Therapeutic Measures**

Thrombolytic agents such as alteplase (Actkase) or reteplase (Retavase) may be used in life-threatening emergencies to dissolve the clot; heparin is used to prevent new clots from forming. Thrombolytics must be administered within 4 to 6 hours of the clot’s occurrence and are associated with risk for hemorrhage.

In patients who cannot tolerate a thrombolytic agent, the clot may be removed with a cardiac catheter, or a surgical embolectomy can be performed. This is a rare procedure that is reserved for emergency situations.

Oxygen is administered even if SpO2 is normal, because it may help dilate pulmonary vessels. Intubation and mechanical ventilation may be required in some cases.

Long-term use of anticoagulants follows initial treatment to prevent formation of additional clots. Initially, heparin, a potent anticoagulant medication, is administered via continuous IV infusion. Sometimes an intermittent IV or subcutaneous route is used. Clotting studies are monitored and maintained at 1.5 to 2 times the control value. Sometimes heparin therapy is initiated even before a diagnosis of PE is made. It is believed that it is safer to begin therapy and then stop if PE is ruled out than to wait until all test results are available.

An oral anticoagulant is used for at least 3 to 6 months after PE to prevent recurrence. It can also be used for long-term prevention of repeated clots in patients who have risk factors that cannot be resolved. Oral therapy can begin 2 to 3 days after the heparin therapy begins. Because it has a slow onset of action, it may take several days for the full anticoagulant effect to occur. See Chapter 23 for nursing care of patients on anticoagulant therapy.

If clots are a recurring problem, a filter may be placed into the inferior vena cava via the jugular or femoral vein to filter out clots traveling from the lower extremities toward the heart and lungs.

**Nursing Process for the Patient With a Pulmonary Embolism**

**DATA COLLECTION.** Assess the patient for respiratory distress, including respiratory rate and effort, cyanosis, confusion, chest pain, and subjective feelings of dyspnea and anxiety.

Auscultate lung sounds. Note sputum color and amount, watching especially for hemoptysis. Monitor ABGs and oxygen saturation. Monitor heart sounds and peripheral edema for signs of heart failure. Contributing factors, such as calf pain, should be noted. Remember, any sudden onset of dyspnea should be taken seriously and reported quickly.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.** The priority nursing diagnosis for a patient with a pulmonary embolism is *Impaired Gas Exchange* (see the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder” for interventions). Because of the impaired perfusion of the affected area of the lung, oxygen and carbon dioxide exchange are limited. Anxiety occurs related to dyspnea. Risk for injury related to anticoagulant therapy is a concern once treatment is initiated (also see Chapter 23).

**Risk for Injury (Bleeding) related to anticoagulant therapy**

**EXPECTED OUTCOME:** The patient will remain safe as evidenced by absence of bleeding. The patient will verbalize understanding of self-care measures.

- Monitor coagulation studies and report results to the HCP.
- Anticoagulant therapy may be adjusted as often as every 6 hours on the basis of laboratory results.
- Protect the patient from injury so that excessive bleeding does not occur.
- Encourage the patient to wear shoes or slippers when ambulating to protect from injury.
- Teach patient to use a soft toothbrush and an electric razor to prevent injury.
- Avoid use of intramuscular (IM) injections. An IM injection can result in hematoma in an anticoagulated patient.
- Instruct the patient to report any signs of bleeding, such as hematuria or easy bruising. Bleeding may be associated with excessively prolonged clotting and may require a change in anticoagulant dosing or administration of an antidote.

**EVALUATION.** The patient should state that dyspnea and anxiety are resolved and verbalize understanding of anticoagulant therapy and precautions. (See Table 31.7 for a pulmonary embolism summary.)

**CHEST TRAUMA**

**Pneumothorax**

The term *pneumothorax* literally means “air in the chest” and is used to describe conditions in which air has entered the space between the visceral and parietal pleurae. If the pneumothorax occurs without an associated injury, it is called a spontaneous pneumothorax. A secondary spontaneous pneumothorax may occur due to underlying lung disease. Traumatic pneumothorax results from a penetrating chest injury. Iatrogenic (caused by medical treatment) pneumothorax results from complications.
of hospital procedures such as central line insertion, pleural biopsy, or positive pressure ventilation.

Pathophysiology and Etiology
Recall that the lungs are surrounded by the visceral and parietal pleurae. These membranes are normally separated only by a thin layer of pleural fluid. Each time a breath is taken in, the diaphragm descends, creating negative pressure in the thorax. This negative pressure pulls air into the lungs via the nose and mouth. If either the visceral pleura or the chest wall and parietal pleura are perforated, air will enter the pleural space, negative pressure will be lost, and the lung on the affected side will collapse (Fig. 31.13). Each time the patient takes a breath, the temporary increase in negative pressure will draw more air into the pleural space via the perforation. During exhalation, air may or may not be able to escape through the perforation.

SPONTANEOUS PNEUMOTHORAX. If no injury is present, the pneumothorax is considered spontaneous. This occurs mostly in tall, thin individuals and in smokers. Patients who have had one spontaneous pneumothorax are at greater risk for a recurrence. Patients with underlying lung disease (especially emphysema) may have blister-like defects in lung tissue (called bullae or blebs) that can rupture, allowing air into the pleural space. Weakened lung tissue from lung cancer can also lead to pneumothorax.

TRAUMATIC PNEUMOTHORAX. Penetrating trauma to the chest wall and parietal pleura allows air to enter the pleural space. This can occur as a result of a knife or gunshot wound or from protruding broken ribs.
symptoms of shock. Tension pneumothorax is often related to the high pressures present with mechanical ventilation. It is a life-threatening emergency.

**HEMOTHORAX.** The term hemothorax refers to the presence of blood in the pleural space. This can occur with or without accompanying pneumothorax (when they occur together it is called a hemothorax) and is often the result of traumatic injury. Other causes include lung cancer, PE, and anticoagulant use.

**Signs and Symptoms**
Sudden dyspnea, chest pain, tachypnea, tachycardia, restlessness, and anxiety occur with pneumothorax. On examination, asymmetrical chest expansion on inhalation may be noted. Breath sounds may be absent or diminished on the affected side. In a “sucking” chest wound, air can be heard as it enters and leaves the wound.

If tension pneumothorax develops, the patient becomes hypoxic and hypotensive as well. The trachea may deviate to the unaffected side. Heart sounds may be muffled. Bradycardia and shock occur if emergency intervention is not provided.

**Diagnostic Tests**
History, physical examination, ultrasound, chest x-ray examination, and CT scan can be used to diagnose pneumothorax. In the emergency department, bedside ultrasound can shorten the time required for diagnosis and intervention and avoid the wait for a chest x-ray to be completed. Chest x-ray examination may be done to monitor the resolution of the pneumothorax after treatment. Arterial blood gases and oxygen saturation are monitored as needed throughout the course of treatment.

**Therapeutic Measures**
A small pneumothorax may absorb with no treatment other than rest or high-flow oxygen, or the trapped air can be removed with a small-bore needle inserted into the pleural space. Chest tubes connected to a water seal drainage system are used to remove larger amounts of air or blood from the pleural space. See Chapter 29 for complete information about chest drainage. Smaller devices that have special one-way valves to allow air to escape but not reenter the chest may be used for some patients who are treated at home. Some injuries require surgical repair before the pneumothorax can be resolved. Oxygen and positioning help maintain oxygenation.

If the pneumothorax is recurrent, other treatments can be used to prevent additional episodes. Sterile talc or certain antibiotics (such as doxycycline) can be injected into the pleural space via thoracentesis, irritating the pleural membranes and making them stick together. This is called pleurodesis, or sclerosis, and prevents recurrent pneumothorax. Pleurodesis is painful; prepare the patient with an analgesic before the procedure.

**Nursing Care of the Patient With a Pneumothorax**
Nursing care of the hospitalized patient with a pneumothorax involves close monitoring of the condition. Frequent and thorough assessments should be done, including level of consciousness, skin and mucous membrane color, vital signs, oxygen saturation, respiratory rate and depth, and presence of dyspnea, chest pain, restlessness, or anxiety. Regular auscultation of lung sounds provides information about reinflation of the affected lung. Be especially vigilant for signs of increasing or tension pneumothorax, and report them to the HCP immediately. Nursing diagnoses to consider include Impaired Gas Exchange, Acute Pain, and Anxiety. See Chapter 29 for care of patient with a chest tube and water seal drainage system. See Table 31.8 for a pneumothorax summary.

**Rib Fractures**

**Etiology and Signs and Symptoms**
Chest trauma is often accompanied by fractured ribs. Uncontrolled coughing, especially in the presence of osteoporosis or cancer, can also fracture ribs. Falls are a common cause of broken ribs in older people. The fourth through ninth ribs are the most commonly affected. Broken ribs can be painful and often prevent the patient from breathing deeply or coughing effectively, which can result in atelectasis or pneumonia. Displaced ribs can also damage abdominal organs or lung tissue, causing pneumothorax.

**Therapeutic Measures**
In the past, elastic rib belts were used to stabilize the ribs while healing took place. These are no longer used because it restricts deep breathing. Pain control is the most important treatment.

**TABLE 31.8 PNEUMOTHORAX SUMMARY**

**Priority**

- Impaired Gas Exchange
- Acute Pain
- Anxiety
Keeping the patient comfortable allows coughing and deep breathing, which in turn prevents complications such as pneumonia and atelectasis. If traditional pain control measures such as NSAIDs or opioids are ineffective, intercostal nerve blocks may be used. Ribs generally heal in about 6 weeks.

**Flail Chest**

**Pathophysiology and Etiology**

When multiple ribs are fractured, the structural support of the chest is impaired. As a result, the affected part of the chest collapses with the negative pressure of inhalation and bulges with exhalation. This is called *paradoxical respiration*, which may be ineffective in ventilating the lungs and result in hypoxia.

**Signs and Symptoms**

The patient with a flail chest exhibits chest movement that is opposite to that usually seen with respiration. The patient is dyspneic and anxious and may also be tachypneic and tachycardic.

**Therapeutic Measures**

Treatment includes supplemental oxygen and analgesics. Intubation and mechanical ventilation may be necessary but are avoided if possible because of related risk for infection. If lung damage has occurred, treatment for pneumothorax may be needed. Surgical stabilization of the ribs may be done in some cases.

### RESPIRATORY FAILURE

**Acute Respiratory Failure**

**Pathophysiology**

Acute respiratory failure is diagnosed when the patient is unable to maintain adequate blood gas values. Hypoxemia may result from inadequate ventilation (air movement in and out of lungs) or poor oxygenation (adequate ventilation but inability to get the oxygen into the blood and therefore the cells) or both. Hypercapnia and respiratory acidosis occur when the diseased lungs are unable to effectively eliminate carbon dioxide.

**Etiology**

An acute respiratory infection in a patient with chronic obstructive disease is often the precipitating factor in acute respiratory failure. Other causes include central nervous system (CNS) disorders that affect the muscles of breathing, such as a stroke, spinal cord injury, or myasthenia gravis; inhalation of toxic substances; opioid overdose; and aspiration.

**Prevention**

Avoidance of respiratory infections in patients with chronic respiratory disease is important. Instruct patients to notify their HCP immediately if sputum becomes purulent so treatment can be initiated.

Sedatives and narcotics should be used carefully or avoided in patients with chronic respiratory disease because these are respiratory depressants and can precipitate failure. Careful monitoring and early intervention are essential in patients at risk for respiratory failure.

**Signs and Symptoms**

The patient with impending respiratory failure may become restless, confused, agitated, or sleepy. Arterial blood gases
Acute respiratory distress syndrome (ARDS) is a group of disorders that has diverse causes but similar pathophysiology, symptoms, and treatment.

Pathophysiology and Etiology
ARDS occurs because of acute lung injury (ALI). The most common cause of injury is widespread sepsis. Other causes include pneumonia, trauma, shock, narcotic overdose, inhalation of irritants, burns, pancreatitis, and aspiration. Each of these causes begins a chain of events leading to alveolo-capillary damage and noncardiogenic pulmonary edema (pulmonary edema that is not caused by heart failure). ARDS usually affects patients without a previous history of lung disease.

Tired respiratory muscles, in combination with edema and atelectasis, reduce gas exchange and result in hypoxia. As the condition progresses, atelectasis and edema worsen and the lungs may hemorrhage. A chest x-ray examination appears white because of the excessive fluid in the lungs. These changes explain some of the older names for what is now known as ARDS: wet lung, white lung, shock lung, and stiff lung.

Prevention
Early recognition and treatment of underlying disorders is important in prevention of ARDS. Good nursing care can help reduce aspiration and some types of pneumonia.

Signs and Symptoms
The patient presents with dyspnea, tachypnea, and cyanosis. Initial respiratory alkalosis (from tachypnea) develops into acidosis as the patient tires. Fine inspiratory crackles are auscultated. The patient is often confused and lethargic. If ARDS is not reversed, eventually hypoxemia leads to decreased cardiac output, shock, and death.

Complications
Complications that can result from ARDS include heart failure, pneumothorax related to mechanical ventilation, infection, and disseminated intravascular coagulation (DIC). The death rate for ARDS in the past was 100%. With newer treatments, it is now closer to 40%. Most patients who survive ARDS recover completely.

Diagnostic Tests
Diagnosis is made based on history of a causative injury, physical examination, chest x-ray examination, CT scan, and blood gas analysis. An ECG is done to rule out a cardiac-related cause.

Therapeutic Measures
The patient with ARDS is cared for in an ICU. Treatment is supportive and also aimed at the underlying cause. Oxygen therapy is adjusted on the basis of repeated ABG results. Non-invasive positive pressure ventilation or intubation and mechanical ventilation are necessary in most cases, with the use of positive end-expiratory pressure (PEEP) to keep the airways open. Diuretics may be used to reduce pulmonary edema, but care must be taken to prevent fluid depletion. IV fluids are administered if blood pressure or urine output is low. A pulmonary artery catheter may be used to monitor hemodynamic status. If infection or sepsis is the underlying cause, antibiotics are administered. Tube feeding or total parenteral nutrition (TPN) maintain nutritional status while the patient is acutely ill. Positioning the patient with the less involved lung in the dependent position (“good lung down”) allows the better lung to be well perfused with blood and may increase PaO2. Prone positioning has also been shown to increase oxygenation and reduce death rate in patients with ARDS.

Nursing Process for the Patient Experiencing Respiratory Failure

Data Collection
Assess the patient’s degree of dyspnea on a scale of 0 to 10 if the patient is able to participate. Monitor respiratory rate and effort, use of accessory muscles, arterial blood gases, and oxygen saturation values. Note the presence of cyanosis.
Monitor mental status, including restlessness, confusion, and level of consciousness, because reduced oxygenation can produce CNS symptoms. Monitor symptoms of the underlying cause of respiratory failure. If the cause is infectious, monitor temperature and WBC counts; if the infection is respiratory in origin, monitor cough and sputum.

All assessment findings should be compared with earlier data. Even subtle changes in the assessment findings can be significant and should be reported.

**Nursing Diagnoses, Planning, and Implementation**

Priority nursing diagnoses include Impaired Gas Exchange, Ineffective Airway Clearance, and Ineffective Breathing Pattern (see the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder”). Related diagnoses include Activity Intolerance, Anxiety, Disturbed Thought Processes, and Self-Care Deficit.

**Evaluation**

If interventions have been effective, the patient will state that dyspnea is controlled. Mental status will be at baseline for the patient. Airways will be kept clear at all times, and SpO2 and respiratory rate will be within normal limits.

**LUNG CANCER**

Lung cancer is the leading cause of cancer death in the United States for both men and women. In 2009, the most recent year for which statistics are available, 110,190 men and 95,784 women were diagnosed with lung cancer, an increase from 2005; 87,694 men and 70,387 women died from lung cancer (CDC, 2013c).

**Pathophysiology**

Lung cancers originate in the respiratory tract epithelium; most originate in the lining of the bronchi (Fig. 31.14). The four major types of lung cancer are identified by the type of cells that are affected: small cell lung cancer (SCLC), large cell carcinoma, adenocarcinoma, and squamous cell carcinoma. The latter three types are classified as non–small cell lung cancer (NSCLC).

About 20% of lung cancers are SCLC (sometimes called oat cell carcinoma). SCLC grows rapidly and often has metastasized by the time of diagnosis. It is usually caused by smoking and is most often found centrally, near the bronchi. The patient with SCLC has a poor prognosis, with survival time averaging less than 1 year.

The remaining 80% of lung cancers are NSCLC. Large cell carcinoma is a rapidly growing cancer that can occur anywhere in the lungs. It metastasizes early in the disease, so these patients also have a poor prognosis.

Adenocarcinoma occurs more often in women, and most often in the peripheral lung fields. It is slow growing but often is not diagnosed until metastasis has occurred. It is less closely linked with smoking.

Squamous cell carcinoma is the most common form of NSCLC and usually originates in the lining of the bronchi; it metastasizes late in the disease. It is associated with a history of smoking. The prognosis for individuals with squamous cell carcinoma may be better than for some other lung cancers.

**Etiology**

Tobacco smoke causes 80% to 90% of lung cancers. Cigarettes contain chemicals that cause DNA to mutate, creating changes in cells and development of tumors. If a patient stops smoking, the risk of lung cancer decreases significantly. Unfortunately, even with all this information, 19% of adults in the United States continue to smoke (CDC, 2013d).

Environmental tobacco smoke has also been shown to cause lung cancer. It is estimated that about 3,400 lung cancer
deaths, 46,000 heart disease deaths, and 430 sudden infant death syndrome deaths occur each year due to environmental tobacco smoke (National Cancer Institute, 2007). Other factors that contribute to increased lung cancer risk are exposure to asbestos, radon, arsenic, air pollution, diesel exhaust, and radiation. Genetic predisposition and a diet poor in fruits and vegetables may also be factors.

**NURSING CARE TIP**

Exposure to radon gas, which can be found in homes, is a significant risk factor for lung cancer. Check out [www.epa.gov/radon/pubs/citguide.html](http://www.epa.gov/radon/pubs/citguide.html) for more information and to find out if radon is a concern in your area. Many local health departments and hardware stores have inexpensive radon test kits available for purchase.

**Ectopic Hormone Production**

Some lung cancers produce *ectopic* hormones that mimic the body’s own hormones. Ectopic production of antidiuretic hormone (ADH) can produce syndrome of inappropriate ADH production (SIADH), which is associated with fluid retention. Ectopic production of adrenocorticotropic hormone (ACTH) can cause Cushing’s syndrome. High calcium levels can be caused by ectopic secretion of a parathyroid-like hormone. These disorders are discussed in Chapter 39.

**Atelectasis and Pneumonia**

Atelectasis occurs when tumor growth prevents ventilation of areas of the lung. Patients with lung cancer also have a greater risk for pneumonia. (See earlier sections on both of these disorders.)

**Metastasis**

Common sites of lung cancer metastasis include the brain, bones, opposite lung, liver, adrenal gland, and lymph nodes.

**Diagnostic Tests**

A complete medical history and physical examination are done to look for symptoms and risk factors for lung cancer. A chest x-ray examination is done to identify a mass. However, all tumors may not show up on a radiograph. A CT or positron emission tomography (PET) scan or MRI may be done to provide more specific information about the size and location of a tumor. Sputum is analyzed for abnormal cells. Brain and bone scans are done to find metastatic lesions. Diagnosis is confirmed with a biopsy of the lesion. A biopsy specimen may be obtained via bronchoscopy, percutaneous biopsy (a needle through the skin guided by radiograph), or mediastinoscopy (placement of an endoscope into the mediastinum to look for changes in mediastinal lymph nodes).

**Therapeutic Measures**

Tumors are staged based on the tumor-node-metastasis (TNM) staging system. Staging helps determine appropriate treatment (Table 31.9). If NSCLC is localized and in an early stage, it may be cured with surgical removal of the tumor. This can be accomplished with a segmental or wedge resection, which removes only the affected lung segment. A *lobectomy* (removal of a lobe) or removal of an entire lung may be done in more advanced cases (Fig. 31.15). Chemotherapy or radiation may be done alone or in addition to surgery. Patients with Stage IV cancer may opt for using experimental drugs in clinical research trials. Palliative surgery may be done to make a patient more comfortable.

Chemotherapy is the treatment of choice in SCLC, because usually it has metastasized by the time of diagnosis. Radiation may be used in combination with chemotherapy.
### TABLE 31.9 STAGES OF LUNG CANCER

<table>

</tbody>
</table>

Surgery is not usually indicated in SCLC; the goal of treatment may be palliation of symptoms rather than cure.

Newer therapies for lung cancer include targeted therapies, such as monoclonal antibodies, antiangiogenesis agents, and growth factor inhibitors. Targeted therapies attack the cancer cells and spare normal cells from damage. Vaccines and gene therapy are also being studied to treat lung cancer.

For more information about cancer treatment and nursing care, see Chapter 11. For more on lung cancer, visit the American Cancer Society at [www.cancer.org](http://www.cancer.org).
NURSING PROCESS FOR THE PATIENT WITH LUNG CANCER

Data Collection
Perform a complete biopsychosocial assessment of the patient with lung cancer. Assess and document respiratory rate and depth, skin and mucous membrane color, lung sounds, oxygen saturation, cough, and sputum amount and character. Ask the patient to rate the degree of pain and dyspnea on appropriate scales. Ask about appetite and weight loss, as well as symptoms of other complications. Note activity tolerance and fatigue.

The patient will likely be grieving about his or her illness and prognosis. Assessment of the patient’s coping strategies and support systems will help you plan care for psychosocial needs. The presence of a living will or durable power of attorney and the desire for assistance with end-of-life planning should be noted (see Chapter 17).

Nursing Diagnoses, Planning, and Implementation
Possible diagnoses that may be experienced by the patient with lung cancer include Impaired Gas Exchange, Ineffective Airway Clearance, Imbalanced Nutrition: Less Than Body Requirements, Pain, Constipation related to opioid use, Anticipatory Grieving, and Activity Intolerance. See the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder” for care of patients with respiratory diagnoses. See Chapter 11 for interventions related to cancer diagnoses.

Evaluation
Carefully consider the patient’s individual goals when evaluating care. Is the patient comfortable and free from unnecessary dyspnea? Is the airway clear, and is nutrition being maintained? Are medication side effects manageable? Have patients with terminal conditions come to terms with their impending death, and have they been able to do those things most important to them before their death? See Table 31.10 for a lung cancer summary.

THORACIC SURGERY
A surgical incision made into the chest wall is called a thoracotomy. A thoracotomy may be performed for a number of reasons, including biopsy; removal of tumors, lesions, or foreign objects; to repair trauma follo wing penetrating or crushing injuries; or to repair or revise structural problems.

Pneumonectomy
A pneumonectomy is the surgical removal of a lung. This is usually done to treat lung cancer. It may also be used to treat severe cases of tuberculosis, bronchiectasis, or lung abscesses. Chest drainage is not usually followed after a pneumonectomy because once the lung is removed, the air in the thoracic cavity is absorbed, and the cavity fills with serosanguineous fluid. At about 6 months after surgery, the fluid is coagulated, and the thoracic cavity is stabilized.

Lobectomy
Lobectomy is the surgical removal of one lobe. This also may be done for lung cancer, tuberculosis, or another localized problem.

Resection
Resection refers to removal of a smaller amount of lung tissue—that is, less than one lobe. A segmental resection is the removal of one segment of a lobe; a wedge resection is removal of a small wedge of lung tissue (see Fig. 31.15).

Video-Assisted Thorascopic Surgery
Video-assisted thorascopic surgery (VATS) is a newer technique that uses a specialized endoscope to perform surgery. It can be done with two or three small incisions, so is much less invasive than a traditional thoracotomy, which requires opening the chest. It can be used for biopsy staging, or treatment of tumors.

Lung Transplantation
Lung transplant can benefit patients with a variety of serious pulmonary disorders, including pulmonary hypertension, emphysema, cystic fibrosis, and bronchiectasis. Either a single lung, both lungs, or heart and lungs have been successfully transplanted. Better criteria for selecting patients and donors, as well as advancements in surgical techniques, have improved outcomes for transplant patients.

pneumonectomy: pneum—lung + ectomy—a—excision
Chapter 31  Nursing Care of Patients With Lower Respiratory Tract Disorders

NURSING PROCESS FOR THE PATIENT UNDERGOING THORACIC SURGERY

Preoperative Nursing Care
Work with the RN to perform a thorough assessment before surgery, with a focus on the respiratory system. This gives a baseline against which to judge changes postoperatively. Routine preoperative teaching is done by the nurse in collaboration with the health team. The patient should understand that he or she will wake up in an intensified care environment. If at all possible, it is helpful to have the patient and family tour the ICU before the surgery to decrease anxiety postoperatively. Prepare the patient for waking up after surgery with an endotracheal tube connected to a ventilator, oxygen, chest tubes, IV fluids, cardiac monitor, Foley catheter, and possibly an epidural catheter for pain control. Let the patient know he or she will not be able to talk while the ET tube is in, and explain the use of the call light, picture board, or alternate communication techniques. Consult the surgeon for specific plans.

Advise the patient that position changes and early ambulation help prevent complications following surgery. Also instruct the patient in the use of incentive spirometry and coughing and deep-breathing techniques for after the endotracheal (ET) tube is removed.

Postoperative Nursing Care

Data Collection
Following thoracic surgery, patients initially are in an ICU. Larger hospitals have special ICUs specifically for surgical or thoracic patients, where patients can be closely monitored for complications. Frequent assessment of vital signs and hemodynamic stability; respiratory rate, depth, and effort; and lung sounds is performed. Remember that lung sounds are absent on the side of a pneumonectomy. An increase in pulse rate or a falling blood pressure may indicate internal bleeding and should be reported immediately. Oxygen saturation is monitored continuously. Often patients report an immediate improvement in breathing because the pulmonary blood supply is no longer being routed to diseased lung tissue.

Assessment for tracheal deviation alerts you to the possible complication of mediastinal shift. The trachea is normally positioned straight above the sternal notch. If the trachea deviates from the midline position, the surgeon should be notified immediately. Secretions are monitored and reported to the HCP if they become thick, yellow or green, or foul smelling. ABGs are monitored closely. Chest tubes are usually present (except following pneumonectomy) and are monitored as explained in Chapter 29. Pain is assessed using a pain rating scale, and incision sites are monitored for redness, edema, or drainage. If the patient is mechanically ventilated, additional assessment of the endotracheal tube and ventilator settings will be needed.

Nursing Diagnoses, Planning, and Implementation

See the “Nursing Care Plan for the Patient With a Lower Respiratory Tract Disorder” for basic interventions. Following are some additional interventions specific to the patient following thoracic surgery.

Ineffective Airway Clearance related to presence of ventilator, inability to cough, and sedation, as evidenced by presence of crackles and wheezes, and high-pressure ventilator alarm

**EXPECTED OUTCOME:** The patient will have a clear airway as evidenced by clear lung sounds and by absence of airway noise and high-pressure ventilator alarms.

- Suction according to agency policy. The airway must remain free of secretions to prevent ventilator-associated pneumonia and dyspnea.
- Once extubated, remind the patient to cough and deep breathe regularly. This helps clear the airway.
- Administer analgesics as ordered. Postoperative pain must be controlled for the patient to be able to cough effectively.

Impaired Gas Exchange related to surgical intervention, opioid use, and removal of lung tissue, as evidenced by ABGs and by SpO2 not within normal limits

**EXPECTED OUTCOME:** The patient’s gas exchange will be within acceptable limits as evidenced by SpO2 of 90% or above.

- Monitor SpO2. Interventions should maintain SpO2 at 90% or above.
- Reposition patient every 1 to 2 hours. Consult surgeon for specific positioning orders. Some surgeons want patients positioned with the operative side up, others with the operative side down. Fowler’s position allows room for lung expansion and helps prevent aspiration.
- Encourage use of an incentive spirometer as ordered following extubation to encourage the patient to deep breathe and maximize oxygenation.
- Monitor chest tube and water seal drainage system, if used. This helps reexpand the lung and must remain intact at all times.
- Administer oxygen and bronchodilators as ordered to maintain oxygenation.

Acute Pain related to surgical procedure as evidenced by pain rating

**EXPECTED OUTCOME:** The patient will be comfortable as evidenced by statement or indication that pain is controlled. If unable to communicate, objective signs of acute pain (increase in vital signs, restlessness) will be absent.

- Administer analgesics as ordered, around the clock. Pain control is important for the patient to be able to ambulate and deep breathe and cough effectively.
- Monitor respiratory rate and effort if not mechanically ventilated. Opioids depress respirations.
- Teach the patient to splint the incision while coughing. This can stabilize the site and reduce pain, increasing the likelihood of effective coughing.

Impaired Physical Mobility related to discomfort at surgical site as evidenced by inability or unwillingness to move

**EXPECTED OUTCOME:** The patient will maintain mobility as evidenced by ability to move arm and shoulder through range-of-motion exercises.
Perform range-of-motion exercises, passively at first, then actively when the patient is able. This helps prevent contracture of the arm and shoulder on the affected side.

Assist the patient to ambulate as tolerated on first or second postoperative day as ordered. Ambulation helps maintain mobility and prevent postoperative complications.

**Risk for Infection related to intubation, Foley catheterization, surgical incision, and major surgery**

**Expected Outcome:** The patient will be free of signs of infection as evidenced by clean and dry incision, temperature and WBC count within normal limits, clear sputum, and clear urine.

- Monitor temperature, WBC count, incision, sputum, and urine for signs of infection so infection can be identified and treated quickly.
- Use standard infection control precautions, including careful hand hygiene, because the patient is at increased risk for infection.
- Use meticulous sterile technique for all invasive procedures: suctioning, dressing changes, catheter insertion. This prevents introduction of pathogens.
- Monitor nutritional intake. Consult dietitian for recommendations. Adequate nutrients are essential for wound healing and immune function.
- Maintain head of bed at minimum 30 degrees elevation to help prevent aspiration of gastric contents.
- Provide frequent oral care to reduce risk of aspiration of oral bacteria.
- Assist with ventilator weaning and extubation as soon as possible. Mechanical ventilation is associated with increased risk of pneumonia.
- Request order to remove Foley catheter as soon as possible. Foley catheter insertion is associated with risk of urinary tract infection (UTI).

**Evaluation**

The patient’s airway should remain clear, and secretions should be easily coughed up. The patient should report an acceptable comfort level and be able to cough, deep breathe, and ambulate without excessive discomfort. The patient’s breathing should be unlabored, with a respiratory rate of 12 to 20 per minute. The patient’s affected arm and shoulder should maintain full range of motion. Urine should be clear. Signs of infection should be absent.
Chapter 31 Nursing Care of Patients With Lower Respiratory Tract Disorders

**SUGGESTED ANSWERS TO CRITICAL THINKING**

**Mr. Smith**
1. A complete respiratory history is taken as described in Chapter 29. An open-ended question such as, “What happened to bring you to the hospital?” elicits information about the incident. In addition, questions to determine mental status and ability to make decisions and function safely on his own are appropriate. If any concerns arise, a social service consultation will be helpful for discharge planning.

2. Mr. Smith should be instructed to always read label warnings before using any cleaning products in the future and to never mix bleach and ammonia!

3. Monitor Mr. Smith closely for signs or symptoms of bacterial pneumonia. Assist with good mouth care, and maintain careful hand-washing and infection-control practices. Discourage ill visitors.

**Mr. Woo**
1. Document exactly what you see: “No redness or induration at either the PPD or Candida test sites.” Date and time your entry, and sign.

2. Everyone has been exposed to, and should react to, Candida with some degree of redness and induration. The fact that Mr. Woo has no reaction at all may mean that his immune system is not working well—he is “anergic.” Therefore, the fact that his PPD test shows no redness and swelling could just be because of his anergy even though he may be infected with TB. So this is an unreliable test for him. Mr. Woo will need a chest x-ray and a sputum culture to be sure he is not infected.

**Mr. Jenkins**
1. Ask questions based on the WHAT’S UP? format: Where (not applicable)

   *How does it feel?* Does the coughing cause chest pain? Are you short of breath?

   *Aggravating and alleviating factors.* What makes the cough worse? What seems to help? Do you use any techniques at home that are helpful?

   *Timing.* How often do you cough during a day? Is it interfering with sleep and rest?

   *Severity.* How bad is it on a scale of 0 to 10? How much sputum are you coughing up? Is it usually this color?

   *Useful other data.* Are you experiencing any other symptoms with your cough (such as shortness of breath, nausea, loss of appetite)?

   *Patient’s perception.* Is it better or worse than usual today? How can I help? (The patient with long-standing disease often knows what will help but is hesitant to ask.)

2. The most appropriate nursing diagnosis is *Ineffective Airway Clearance* related to excessive secretions and ineffective cough.

   Provide hydration with oral liquids and a room humidifier to liquefy secretions. Administer expectorants as ordered. Instruct the patient in coughing and deep-breathing exercises such as autogenic drainage to increase the effectiveness of his cough. Provide good oral care following expectoration of sputum to freshen the patient’s mouth. Obtain an order for chest physiotherapy or a vibratory PEP device (Chapter 29) to help loosen and drain secretions.

3. “Patient expectorated 200 mL of bright yellow, foul-smelling sputum. Lungs have scattered crackles and wheezes throughout after coughing episode. Expectorant given; fluids encouraged. Mouth care provided.”

4. Respiratory therapy should be involved with nebulized mist treatments and assistance with airway clearance interventions. Occupational or physical therapy can help with mobilization and increasing exercise tolerance. Discharge planning may be needed to help set up home therapies. Social work or pastoral care can help with emotional distress related to having a chronic disease.

**Mr. Franklin**
1. You need to do several things at once. You will begin by speaking in a calm voice and trying to help Mr. Franklin to calm himself by doing pursed-lip breathing. Assure him that you will help him and won’t leave. At the same time, check his oxygen to make sure it is on the ordered number of liters and that his tubing is not kinked or disconnected. Grab the bedside table for him to lean on. Call for someone to page a respiratory therapist to do a nebulized mist treatment if ordered. Have someone bring a pulse oximeter to check his oxygen saturation. Also call for the RN to administer IV morphine if ordered. All this should take about 1 minute! Once Mr. Franklin is a bit calmer, you can find out what happened. Did the exertion of moving to the bedside commode cause his dyspnea? Check his vital signs and lung sounds, and work with the RN to determine if this represents a change in Mr. Franklin’s condition that should be reported to the HCP.

2. Teach Mr. Franklin that he should probably stay on bedrest until his acute exacerbation is resolved. Once he is able to start moving around, he should call for help to get up. Review his controlled breathing exercises, which he can use during movement, and encourage rest between activities.

Continued
SUGGESTED ANSWERS TO—cont’d

3. “3:00: Patient up on bedside commode (BSC), respiratory rate (RR) 36 per minute and labored, color gray, appeared very apprehensive. O₂ on at 2 L per min per nasal cannula (NC), assisted to lean on over-bed table. Encouraged pursed-lip breathing. Vital signs (VS) 146/64 mm Hg, 102 beats per minute, 36 per minute, SpO₂ 82%. RT paged; administered as needed (prn) NMT. Breath sounds diminished, no cough. At 3:15, patient appears much calmer, RR 24 per minute and less labored, SpO₂ 90%.”

REVIEW QUESTIONS

1. A patient asks the nurse why he doesn’t feel sick even though his TB test is positive. The nurse knows the patient has been diagnosed with LTBI. Which explanation is best to provide the patient?
   1. “TB often does not make people feel sick, but it is contagious nevertheless.”
   2. “You have latent disease, which just stays in your system but won’t ever make you sick.”
   3. “You have TB infection, but not active disease. As long as your immune system stays strong, it can keep the infection from making you sick.”
   4. “Even though you do not feel sick, the positive test shows that you have the disease and must be treated.”

2. Which of the following assessment findings does the nurse expect in the patient with emphysema?
   1. Purulent sputum
   2. Diminished breath sounds
   3. Generalized edema
   4. Dull chest pain

3. A patient with shortness of breath is being tested for lung cancer. Which diagnostic test will be most conclusive?
   1. Chest x-ray
   2. MRI
   3. Sputum culture
   4. Biopsy

4. A patient with recurrent pneumothorax is scheduled to have pleurodesis done in 1 hour. Which nursing intervention should take priority at this time?
   1. Encourage fluids.
   2. Encourage coughing and deep breathing.
   3. Administer a prn analgesic as ordered.
   4. Administer a prn bronchodilator as ordered.

5. Which of the following assessment findings in the patient with pneumonia most indicates a need to remind the patient to cough and deep breathe?
   1. The patient reports chest pain.
   2. The patient has removed her oxygen.
   3. The patient develops coarse wheezes and crackles.
   4. The patient has a fever of 101°F (38.3°C).

6. A patient is admitted to the hospital with shortness of breath. The nurse notes increasing confusion and combativeness during the past hour. Which of the following actions is appropriate first?
   1. Assess SpO₂ and apply oxygen per protocol if indicated.
   2. Page the physician stat.
   3. Put up the patient’s side rails and apply soft restraints.
   4. Administer a prn dose of intramuscular sedative.

7. Which of the following interventions is most appropriate for the patient with an ineffective breathing pattern?
   1. Encourage the patient to cough and deep breathe.
   2. Teach the patient controlled diaphragmatic breathing.
   3. Encourage oral fluids.
   4. Allow the patient to rest between activities.

8. A patient with end-stage COPD has a nursing diagnosis of Impaired Gas Exchange. Which assessment finding shows that interventions have been effective?
   1. The patient’s SpO₂ is 92% on 2 L of oxygen.
   2. The patient appears comfortable.
   3. The patient is coughing up copious white sputum.
   4. The patient is able to move in bed without difficulty.

Answers can be found in Appendix C.
Chapter 31  Nursing Care of Patients With Lower Respiratory Tract Disorders

Understanding the Gastrointestinal, Hepatic, and Pancreatic Systems
Gastrointestinal, Hepatobiliary, and Pancreatic Systems
 Function, Assessment, and Therapeutic Measures

LEARNING OUTCOMES

1. List the structures of the gastrointestinal tract and of the accessory glands: liver, gallbladder, and pancreas.

2. Describe the functions of each organ of the gastrointestinal tract and of the accessory glands: liver, gallbladder, and pancreas.

3. Discuss how age affects the gastrointestinal tract and accessory glands.

4. List data to collect when caring for a patient with a disorder of the gastrointestinal system, liver, gallbladder, or pancreas.

5. Differentiate normal and abnormal data collection findings.

6. Explain techniques used to conduct a physical examination of the abdomen.

7. Plan nursing care for patients having diagnostic tests of the gastrointestinal tract.

8. Explain types of nasogastric tubes and their uses.

9. Plan nursing care for insertion and maintenance of nasogastric tubes.

10. Describe therapeutic measures used for patients with gastrointestinal diseases.
NORMAL GASTROINTESTINAL, HEPATOBILIARY, AND PANCREATIC SYSTEMS ANATOMY AND PHYSIOLOGY

The gastrointestinal (GI) tract (or alimentary tract) is part of the digestive system (Fig. 32.1). Digestion begins in the oral cavity and continues in the stomach and small intestine. Most absorption of nutrients takes place in the small intestine. The large intestine is where the majority of water is reabsorbed. Indigestible material, mainly cellulose, is then eliminated from the large intestine. Accessory organs include teeth, tongue, salivary glands, liver, gall bladder, and pancreas.

Oral Cavity and Pharynx

The boundaries of the oral cavity are the hard and soft palates superiorly, the cheeks laterally, and the floor of the mouth inferiorly. Within the oral cavity are the teeth, tongue, and the openings of the ducts of the salivary glands.

The teeth begin mechanical digestion to create more surface area for the chemical digestion regulated by enzymes. The roots of the teeth are in sockets in the mandible and maxillae. The tongue is made of skeletal muscle innervated by the hypoglossal nerve. Taste buds surround the base of each papilla. Innervation for tasting is by the facial, glossopharyngeal, and vagus nerves. Elevation of the tongue is the first step in swallowing.

The three pairs of salivary glands are the parotid, submandibular, and sublingual glands. Their ducts secrete saliva to the oral cavity. Salivation is a parasympathetic response mediated by the facial and glossopharyngeal nerves. Saliva is mostly water, which is used to dissolve food for gustation and moisten the food for swallowing. The only digestive enzyme in saliva that functions in the mouth is amylase, which digests starch to maltose. However, food does not remain in the mouth long enough for significant starch digestion. There is also lingual lipase, however, which when activated by acidic pH begins its action in the stomach.
The pharynx is a muscular tube connecting the oral cavity to the esophagus. When a mass of food is pushed posteriorly by the tongue, the smooth muscles of the pharynx contract as part of the swallowing reflex. This reflex is regulated by the medulla and pons. The uvula closes off the nasopharynx while the epiglottis closes the opening to the larynx.

**Esophagus**

The esophagus is about 10 inches long and carries ingested items from the pharynx to the stomach. No digestion takes place in the esophagus. **Peristalsis** of the muscle layer in the wall of the esophagus propels food inferiorly to the stomach. At the junction with the stomach, the lumen of the esophagus is surrounded by the lower esophageal sphincter (LES; also cardiac sphincter, gastroesophageal sphincter, or esophageal sphincter), a circular smooth muscle. The LES relaxes to permit food to enter the stomach; it mainly serves as a reservoir for food so that digestion may take place gradually.

The four regions of the stomach are the cardia, fundus, body, and pylorus (Fig. 32.2). The pylorus is divided into an antrum and canal and narrows at the pyloric sphincter, which guards entry to the duodenum.

When the stomach is empty, the mucosa (inner lining) has folds called rugae that permit expansion of the lining. The mucosa contains gastric pits with glands of the stomach that produce gastric juice.

**Stomach**

The stomach is in the upper left abdominal quadrant, to the left of the liver and in front of the spleen. It is a J-shaped, saclike organ that extends from the esophagus to the duodenum of the small intestine. Some digestion takes place in the stomach; it mainly serves as a reservoir for food so that digestion may take place gradually.

The body, antrum, and canal (Fig. 32.2) are divided by the lesser curvature and greater curvature. The pyloric canal is the part of the stomach that empties into the duodenum.

The stomach is a large muscular sac that stores food temporarily and produces the gastric juice that contains hydrochloric acid and the enzymes pepsin and intrinsic factor. The stomach is divided into four regions: the cardia, fundus, body, and pylorus. The cardia is the inferior end of the esophagus that opens into the stomach. The fundus is the upper portion of the stomach, which is located to the left of the liver and in front of the spleen. The body is a sac-like part of the stomach that stores food temporarily. The pylorus is an angular area that connects the stomach to the duodenum.

When the stomach is empty, the mucosa (inner lining) has folds called rugae that permit expansion of the lining. The mucosa contains gastric pits with glands of the stomach that produce gastric juice. Gastric juice begins secretion at the sight or smell of food; this is a parasympathetic response. The presence of food in the stomach stimulates the secretion of the hormone gastrin by the gastric mucosa. Gastrin increases the secretion of gastric juice.

**Small Intestine**

The small intestine is about 1 inch in diameter and approximately 20 feet long. Within the peritoneal cavity, the coils of the small intestine are encircled by the colon. The small intestine extends from the stomach to the cecum of the colon. The duodenum is the first 10 inches and contains the hepatopancreatic ampulla (ampulla of Vater), the entrance of the common bile duct and the pancreatic duct. The jejunum is about 8 feet long; the ileum is about 11 feet in length.

Digestion is completed in the small intestine, and the end products of digestion are absorbed into the blood and lymph. Bile from the liver and enzymes from the pancreas function in the small intestine (Table 32.1). When chyme enters the duodenum, the intestinal mucosa produces the enzymes sucrase, maltase, and lactase, which complete the digestion of saccharides to monosaccharides; the peptidases, which complete the digestion of proteins to amino acids; and the nucleosidases and phosphatases, completing nucleotide digestion.

The absorption of nutrients requires a large surface area; the small intestine has extensive folds for this purpose. Macroscopic circular folds and microscopic villi with apical border microvilli greatly expand the absorptive surface. Water-soluble nutrients (monosaccharides, amino acids, minerals, water-soluble vitamins) are absorbed into the blood in the capillary networks. Fat-soluble vitamins and fatty acids and glycerol are absorbed into the chyle of the lacteals.

**Large Intestine**

The large intestine extends from the ileum of the small intestine to the anus. It is about 5 feet long and 2.5 inches in diameter. No further digestion takes place in the colon; it temporarily stores and then eliminates indigestible material. The mucosa absorbs significant amounts of water and minerals, as well as the vitamins produced by the normal bacterial flora.

Elimination of feces is accomplished by voluntary and voluntary actions. Parasympathetic control initiates the defecation reflex, from centers in the sacral region of the spinal cord. Baroreceptor input produces returning motor impulses, which cause contraction of the smooth muscle of the rectum and relaxation of the internal anal sphincter. Voiding is voluntarily controlled via actions of the external anal sphincter.

**Word Building**

**peristalsis:** peri—around + stellein—to place
Liver

The liver occupies the right side and center of the upper abdominal cavity just below the diaphragm. Its right lobe is larger than the left lobe.

The blood supply of the liver differs from that of other organs. The liver receives oxygenated blood by way of the hepatic artery. By way of the hepatic portal vein, blood from the abdominal digestive organs and the spleen is brought to the liver before being returned to the heart. This special pathway is called hepatic portal circulation and permits the liver to regulate blood levels of nutrients or to remove potentially toxic substances such as alcohol from the blood before the blood circulates to the rest of the body. All blood leaving the liver exits via the hepatic vein.

The only digestive function of the liver is the production of bile by the hepatocytes. Bile flows to the duodenum via ducts from either the liver or gall bladder (Fig. 32.3).

Bile is mostly water and bile salts. Its excretory function is to carry bilirubin and excess cholesterol to the intestines for elimination in feces. The digestive function of bile is accomplished via bile salts, which emulsify fats in the small intestine. Emulsification is a type of mechanical digestion in which large fat globules are broken into smaller globules producing greater surface area for chemical catabolism. Secretion of bile is stimulated by the hormone secretin and ejection of bile from the gallbladder is stimulated by cholecystokinin.

Functions of the Liver

The liver is involved in a great variety of functions, most of which involve organic molecule metabolism. These functions can be grouped into categories.

CARBOHYDRATE METABOLISM. The liver regulates the blood glucose level by storing excess glucose as glycogen and performing glycogenolysis when the blood glucose level is low. The liver also changes other monosaccharides to glucose, which is more readily used by cells for energy production.

AMINO ACID METABOLISM. The liver regulates the blood levels of amino acids based on tissue needs for protein synthesis. Of the 20 amino acids needed for the production of human proteins, the liver is able to synthesize 12, called the nonessential amino acids, by the process of transamination. The other 8 amino acids, which the liver cannot synthesize, are called the essential amino acids. Essential amino acids are required in the diet.

Excess amino acids (those not needed for protein synthesis) undergo the process of deamination in the liver; the amino group is removed, and the remaining carbon chain is converted to a simple carbohydrate that is used for energy production or converted to fat for energy storage. The amino groups are converted to urea, a nitrogenous waste product that is removed from the blood by the kidneys and excreted in urine.

LIPID METABOLISM. The liver forms lipoproteins for the transport of lipids in the blood to other tissues. The liver also synthesizes cholesterol and excretes excess cholesterol into bile to be eliminated in feces.

Beta oxidation is another task of the liver, in which fatty acid molecules are split into two-carbon acetyl groups. These acetyl groups may be used by the liver to produce energy, or they may be combined to form ketones to be transported to other cells for energy production.

SYNTHESIS OF PLASMA PROTEINS. The liver synthesizes albumin, clotting factors, and globulins. Albumin, the most abundant plasma protein, maintains osmotic balance. Clotting factors produced by the liver include prothrombin and fibrinogen, which circulate in the blood until needed for coagulation. Globulin functions include becoming part of lipoproteins, acting as carriers, and acting as antibodies.

PHAGOCYTOSIS BY KUPFFER CELLS. The fixed macrophages of the liver (named Kupffer cells or stellate reticuloendothelial cells), phagocytize worn formed elements and pathogens.

</table>
FORMATION OF BILIRUBIN. Hepatocytes form bilirubin from the heme portion of hemoglobin removed from worn erythrocytes and collect bilirubin from the spleen. Bilirubin is excreted as a part of bile to be eliminated in feces.

STORAGE. The liver stores the minerals iron and copper; the fat-soluble vitamins A, D, E, and K; and the water-soluble vitamin B12.

DETOXIFICATION. The liver synthesizes enzymes that convert harmful substances to less harmful ones. Alcohol and medications are examples of potentially toxic chemicals. The liver also converts ammonia from protein metabolism to urea, a less toxic substance.

ACTIVATION OF VITAMIN D. The skin, kidneys, and liver each perform a role in providing the body with activated vitamin D.

Pancreas
The pancreas is about 6 inches long and is located posterior to the greater curvature of the stomach. Digestive secretions enter the duodenum either via the pancreatic duct or the alternate accessory duct (see Fig. 32.3).

The pancreatic digestive enzymes are involved in the digestion of all four of the organic molecule categories. The enzyme pancreatic amylase digests starch to maltose. Pancreatic lipase converts emulsified fats to fatty acids and monoglycerides. Trypsinogen is an inactive enzyme that is changed to active trypsin in the duodenum. Trypsin digests polypeptides to shorter chains of amino acids. Pancreatic juice also contains proteolytic enzymes: chymotrypsin, carboxypeptidase, and elastase. Ribonuclease and deoxyribonuclease, for the digestion of RNA and DNA, respectively, are contributed by the pancreas as well.

Secretion of pancreatic juice is stimulated by the hormones of the duodenal mucosa. Secretin stimulates the production of bicarbonate pancreatic juice, and cholecystokinin stimulates secretion of the pancreatic enzyme juice.

Gallbladder
The gallbladder is a muscular sac approximately 4 inches long located on the undersurface of the liver. Bile in the common hepatic duct from the liver flows through the cystic duct into the gallbladder, which stores bile until it is needed in the small intestine (see Fig. 32.3). The gallbladder concentrates bile by absorbing water.

When fatty foods or partially digested proteins enter the duodenum, the duodenal mucosa secretes the hormone cholecystokinin. One function of cholecystokinin is to stimulate contraction of the smooth muscle of the wall of the gallbladder. Contraction of the gallbladder forces bile into the cystic duct, then into the common bile duct, which empties into the duodenum.

Aging and the Gastrointestinal, Hepatobiliary, and Pancreatic Systems
Many changes occur in the aging gastrointestinal (GI) system (Fig. 32.4). The sense of taste becomes less acute, and the likelihood of developing periodontal disease or oral cancer increases. If teeth have been lost, an older person may experience difficulties with chewing. Secretions throughout the GI tract are reduced, and the effectiveness of peristalsis diminishes because of loss of muscle elasticity and slowed motility. Indigestion may become more common, especially...
if the LES loses its tone, and peptic ulcers are more common. In the colon, diverticula may form. Constipation may be a problem, as may hemorrhoids. The risk of colon cancer also increases with age.

The liver usually continues to function well into old age, unless damaged by pathogens such as the hepatitis viruses or by toxins such as alcohol (“Gerontological Issues”). There is a greater tendency for gallstones to form, sometimes necessitating removal of the gallbladder. In the absence of specific pathological conditions, the pancreas usually functions well, although acute pancreatitis of unknown cause is somewhat more common in older adults.

NURSING ASSESSMENT OF THE GASTROINTESTINAL, HEPATOBILIARY, AND PANCREATIC SYSTEMS

Health History

Assessment of current signs and symptoms includes asking the WHAT’S UP? questions as presented in Chapter 1 (Tables 32.2 and 32.3). Demographic data are obtained, including travel history, which may help in diagnosing the cause of GI symptoms such as diarrhea.

Ask the patient about any nausea, vomiting, or abdominal distention. Information about the timing or other common triggers of episodes of nausea or vomiting may help the practitioner identify their cause. Such information may also help determine appropriate treatment for any future nausea or vomiting. Abdominal distention in the presence of nausea

Gerontological Issues

With increasing age, the liver decreases in volume, mass, and blood flow. These changes are significant because the liver acts to metabolize many drugs. If a patient has impaired liver function, toxic levels of a drug may be present in the blood. It is important to assess liver function tests and perform a medication review to determine those that are metabolized by the liver. Older adults may require reduced doses of many drugs.

FIGURE 32.4 The effects of aging on the gastrointestinal, hepatic, and pancreatic systems is shown on this concept map.

</table>

*Note: GI = gastrointestinal; NSAID = nonsteroidal anti-inflammatory drug.*

and vomiting may indicate intestinal obstruction. Patients with liver, gallbladder, or pancreatic disease may also report feeling bloated, having gas or belching frequently, or right upper quadrant (RUQ) tenderness.

Question the patient about any observed changes in bowel elimination. Diarrhea may be caused by irritation of the bowel. Constipation may indicate decreased water intake or excessive water loss. Observe the patient’s stool for evidence of bacteria (a foul smell), flat (stool floats on the water surface and appears greasy), pus, blood, or mucus. Patients with liver or gallbladder disease may have pale or clay-colored stools.
Determine if the patient has had any recent blood transfusions or blood products, dental procedures, body piercing or tattooing, or intravenous (IV) injection with a potentially contaminated needle. These procedures cause a break in the skin that can become an entry point for hepatitis virus (type B or C) as well as other pathogens.

Ask about the patient’s usual work activities and work setting. Document exposure to chemicals such as paint fumes, industrial dyes, acids, farm pesticides, or other liver-toxic substances.

Investigate the patient’s activities other than work. Document reports of fatigue along with information about when the fatigue occurs. Ask the patient about stressors such as financial concerns, problems dealing with the health care environment, and any family or personal problems. Attempt to determine what coping mechanisms the patient usually employs to deal with stressors.

**Medications**

The patient is asked about medication use such as nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, vitamins, laxatives, enemas, or antacids. Heavy use of medications that can cause irritation and bleeding in the GI tract, such as NSAIDs or aspirin, should be carefully noted. Older patients with arthritis often use these types of medications for pain control. The patient’s knowledge of the side effects of these medications should be assessed to identify important teaching needs. Older patients may use laxatives regularly and develop a dependence on them. Teaching may be needed on normal bowel patterns and laxative use. Also ask the patient what medications are being taken with or without a health care provider’s (HCP’s) prescription, such as acetaminophen, which can be hepatotoxic. Many people do not consider it necessary to report over-the-counter preparations and herbal, natural, or other nonprescription products and must be asked specifically about them.

**CLOSTRIDIUM DIFFICILE.** Question the patient about uncontrolled diarrhea, recent hospitalizations, or antibiotic use. Hospitalization or recent antibiotic use is a risk factor for Clostridium difficile (see Chapter 8). With antibiotic use, a decrease in normal flora can result, allowing an overgrowth of C. difficile. The toxins produced by C. difficile can cause...
diarrhea, colitis, toxic megacolon, dehydration, or colonic perforation. Monitor patients closely for signs of *C. difficile* infection such as diarrhea, nausea, anorexia, and abdominal tenderness or pain. Report these symptoms to the HCP because this infection can be fatal.

**CRITICAL THINKING**

Mrs. Todd

- Mrs. Todd, age 74, has arthritis and takes eight aspirin daily for pain control. She is scheduled for an esophagogastroduodenoscopy (EGD) for suspected GI bleeding causing unexplained anemia.

1. What is a likely cause of the GI bleeding?
2. What could you do to help prevent future bleeding episodes for Mrs. Todd?
3. What nursing care will need to be completed before the test and after the test?

*Suggested answers are at the end of the chapter.*

**Nutritional Assessment**

A diet history should include usual foods and fluids, allergies, appetite patterns, swallowing difficulty, and use of nutritional and herbal supplements. A food diary can be used to provide more detailed information. Older patients may be on fixed incomes, which may limit their food budget and result in meal skipping or purchasing of inexpensive foods. The older patient’s daily food intake should be explored, especially if malnutrition, financial limitations, or living alone is noted.

Also explored during a nutritional assessment are patterns of gastric acid reflux, indigestion, heartburn, nausea, vomiting, diarrhea, constipation, flatulence, and bowel incontinence, all of which may interfere with proper nutrition ("Gerontological Issues"). Acid reflux can be assessed by asking patients if they experience reflux with a bile taste or a waken with an unpleasant taste in their mouth.

**Family History**

Family history of close relatives with conditions that may influence the patient’s GI status is noted. Some GI problems such as colon cancer are thought to be hereditary. The patient’s history should note whether there is a family history of liver, pancreas, or gallbladder diseases, such as diabetes mellitus, alcoholism, cancer, heart disease, or bleeding tendencies. These diseases tend to run in families.

**Cultural Influences**

Many cultures have special dietary practices and restrictions ("Cultural Considerations"). See Box 32-1, “Cultural Assessment Questions,” for assessment questions. Understanding these cultural influences, respecting them, and assisting the patient to maintain desired cultural practices are important for nutritional maintenance.

**Gerontological Issues**

A complete bowel history should be obtained for older adults before beginning a bowel program. A bowel history includes the following:

- Normal bowel evacuation pattern
- Characteristics of stool
- Presence of any bleeding or mucus with the stool
- Use of products and medications to stimulate or slow bowel function
- Report of usual diet
- Amount of fluids—number and size of beverages, glasses per day (beverages containing caffeine, such as coffee, tea, and sodas, do not count as fluids because of the diuretic effect of caffeine)
- Exercise and physical activity

Patients with disease of the liver, pancreas, or gallbladder commonly have changes in appetite such as anorexia or alterations in eating preferences. Ask the patient about any abnormal weight loss or unexpected weight gain and changes in food tolerance, including the type or amount of offending foods. For example, patients with gallbladder disease may report that they feel nauseated or bloated after eating fried or greasy foods. Ask if the patient smokes, ingests alcohol, or uses other recreational drugs. If the patient acknowledges alcohol or other drug use, record the type, frequency, and amount used.

**Box 32-1 Cultural Nutritional Assessment**

Questions to ask when performing a cultural nutritional assessment:

- What types of your cultural foods are available in your community?
- What are your preferred foods over foods available and eaten?
- Which foods do you most commonly consume?
- How and where are your foods chosen and purchased?
- Who prepares the food in your household?
- Who purchases the food in your household?
- How is your food stored for future use?
- How is your food prepared before being eaten?
- How is any uneaten food discarded?
- What foods do you eat to maintain your health?
- What foods do you avoid to maintain your health?
- What foods do you eat when you are ill?
- What foods do you avoid when you are ill?
### Cultural Considerations

#### African Americans
Obesity is seen as positive among many African Americans. They often view individuals who are thin as “not having enough meat on their bones.” One needs to have adequate meat on his or her bones so that when an illness occurs, one can afford to lose weight. Many African American diets are high in animal fat and fried foods and low in fiber, fruits, and vegetables.

#### Appalachians
The diet of some Appalachians is deficient in vitamin A, iron, and calcium. The nurse working with this population needs to do a dietary assessment and teach patients food selections that include adequate vitamin A, iron, and calcium.

#### Arabs
Many Arabs eat food only with their right hand because it is regarded as the clean hand. The left hand, commonly used for toileting, is considered unclean. Thus, the nurse should feed the Arab patient with the right hand regardless of the nurse’s dominant handedness. Additionally, some may not drink beverages with their meals because some consider it unhealthy to eat and drink at the same meal. Likewise, mixing hot and cold foods may be seen as unhealthy.

Muslim Arabs may refuse to eat meat that is not *halal* (slaughtered and prepared in a ritual manner). Because Muslim Arabs are prohibited from ingesting alcohol or eating pork, they may refuse medication that includes alcohol, such as mouthwashes, toothpaste, alcohol-based syrups and elixirs, and products derived from pigs, such as insulin, gelatin-coated capsules, and skin grafts. However, if no substitute is available, Muslims are permitted to use these preparations.

The condition of the alimentary tract has priority over all other body parts in the Arab’s perception of health. GI problems are the most common reasons for which Arab Americans seek care.

#### Asian Indians
Among Asian Indians, nutritional deficiencies are patterned from the region of emigration. For example, *beriberi* (thiamine deficiency) is found in people emigrating from rice-growing areas. Pellagra (niacin deficiency), causing skin and mental disorders and diarrhea, is found in people emigrating from maize-millet areas. Thorough milling of rice, washing rice before cooking, and allowing the cooked rice to remain overnight before consumption the following day result in the loss of thiamine.

Asian Indians use chili, which may make it difficult for them to eat food that is tasteless, or the use of chili may cause problems with upper GI conditions.

The commitment to the sacred cow concept encourages dairy and milk use by Hindus. However, lactose intolerance affects more than 10% of adults. The adequacy or inadequacy of the ability to digest lactose may be due to genetic differences among Asian Indians.

Goiter is prevalent among some Asian Indian immigrants as a result of an iodine deficiency in food and water from their homeland. Fluorosis occurs in other parts of India from drinking water high in fluoride. Osteomalacia is prevalent where diets are deficient in calcium and vitamin D. Endemic dropsy is prevalent among Asian Indians emigrating from West Bengal, resulting from the use of mustard oil for cooking. The nurse needs to be aware of these conditions and their causes when working with Hindus and Asian Indians and teach patients prevention.

#### Brazilians
Brazilians experience an increase in GI distress when they first come to the United States, partially because many have a lactose intolerance and partially because of different methods of milk pasteurization. The nurse can assist with identifying alternative food sources for Brazilian patients to obtain needed calcium in their diet.

#### Jews
Among Jews, the laws regarding food are commonly referred to as the laws of Kashruth, or the laws of what foods are permissible in accordance with the religious law. The term *kosher* means “fit for eating”; it is not a brand or form of cooking.
Cultural Considerations—cont’d

Foods are divided into those that are permitted (clean) and forbidden (unclean). The kosher slaughter of animals prevents undue cruelty to the animal and ensures the animal’s health for its consumer. Care must be taken that all blood is drained from the animal before eating it.

Among the more conservative and Orthodox Jews, dairy products and meat may not be mixed together, whether in cooking, serving, or eating. This involves separating the utensils used to prepare foods and the plates used to serve them. To avoid mixing foods, religious Jews have two sets of dishes, pots, and utensils: one set for dairy products and one for meat.

Cheeseburgers, meat lasagna, and grated cheese on meatballs and spaghetti are not acceptable. Milk cannot be used in coffee if served with a meat meal. Nondairy creamers can be used as long as they do not contain sodium caseinate, which is derived from milk.

Fish, eggs, vegetables, and fruits are considered neutral and may be used with either dairy or meat dishes. A “U” with a circle around it or a “K” is used on food products to indicate that a food is kosher.

When working in a Jewish person’s home, the nurse should not bring food into the house without knowing whether the patient is kosher. If the patient is kosher, do not use any cooking items, dishes, or silverware without knowing which are used for meat and which are used for dairy. It is important for the nurse to understand the dietary laws so as not to offend the patient. The nurse should advocate for kosher meals if they are requested and plan medication times accordingly.

Although nonreligious Jews decide for themselves which dietary laws, if any, they follow, many still avoid pork and pork products out of a sense of tradition and symbolism. It would be insensitive to serve pork products to Jewish patients unless they specifically request them.

Kosher meals are available in hospitals and long-term care facilities. Even though the organization may not have a kosher kitchen, frozen kosher meals can be obtained from several organizations, most of which are located in large cities with large Jewish populations. The address and telephone number of the kosher kitchen closest to your organization can be obtained by calling the nearest Jewish synagogue. Kosher meals arrive on paper plates with plastic utensils sealed in plastic. The nurse should not unwrap the utensils if the patient is able to do so or change the foodstuffs to another serving dish. Determining a patient’s dietary preferences and practices regarding dietary laws should be done during the admission assessment.

Mexican Americans

Good health to Mexican Americans, which is largely a part of “God’s will,” can be maintained by dietary practices that keep the body in balance. To provide culturally competent care, the nurse must be aware of the hot-and-cold theory of disease when offering health teaching. Many diseases are thought to be caused by a disruption in the hot-and-cold balance theory of the body. Thus, by eating foods of the opposite variety, one may either cure or prevent specific hot-and-cold illnesses and conditions.

Examples of hot disease conditions include infection, diarrhea, sore throats, stomach ulcers, liver conditions, kidney problems, GI upset, and febrile conditions. Foods that are considered “cold” are therefore viewed as remedies for hot illness conditions. Cold foods include fresh fruits and vegetables, dairy products, barley water, fish, chicken, goat meat, and dried fruits. However, significant differences are seen in terms of what are considered hot and cold foods and illnesses among Mexican American families depending on their native region in Mexico.

Examples of cold illness conditions include cancer, malaria, earaches, arthritis and related conditions, pneumonia and other pulmonary conditions, headaches, menstrual cramping, and musculoskeletal conditions. Hot substances used to treat these conditions typically include cheeses, liquor, beef, pork, spicy foods, eggs, grains other than barley, vitamins, tobacco, and onions.

Physical Examination

Table 32.4 summarizes findings from the objective assessment of the GI, hepatobiliary, and pancreatic systems discussed next.

Height, Weight, and Body Mass Index

The patient’s height and weight are obtained for planning care. It is compared with the patient’s ideal body weight obtained using current reference charts. Body mass index (BMI) is calculated to measure body fat and used with waist-to-hip ratio measurements to determine patient’s health risk factors (Table 32.5). Excess waist circumferences (for women, more than 35 inches; for men, more than 40 inches) place people at greater risk for diabetes and cardiovascular disease. Also the location of excess fat, mainly around the waist, increases the risk of health problems even with a normal BMI.
<table>
<thead>
<tr>

<th>Physical Examination Findings</th>
<th>Possible Abnormal Findings/Causes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Height, Weight, and Body Mass Index (BMI)</td>
<td>Normal height, weight and BMI</td>
<td>Decreases in height, weight, and BMI could indicate inadequate nutrition or malabsorption problems. Current weight loss could indicate new onset of a disease such as cancer.</td>
</tr>
<tr>
<td>Oral Cavity</td>
<td>Moist, pink oral mucosa, without lesions, inflammation, tenderness, or discolorations. Pink, rough tongue. Teeth should be intact. Dentures should fit properly.</td>
<td>Foul odor may indicate infection or poor oral hygiene. Dry tongue with cracked furrows could indicate dehydration possibly due to vomiting or diarrhea. Broken teeth or ill-fitting dentures can contribute to inadequate nutrition.</td>
</tr>
<tr>
<td>Abdomen Inspection</td>
<td>Abdomen contour should be flat, rounded, or convex. Shape should be symmetrical. Skin color should be consistent with overall skin tone. No visible scars or discolorations.</td>
<td>Irregularities in contour such as bulging or masses may be due to distention, tumors, hernia, or previous surgeries. Any scars, dressings, appliances such as an ostomy should be noted. Indicate what the stoma looks like. Scars may be present if the patient has had previous surgeries or injuries. Striae are present if the skin has been stretched (i.e., with pregnancy or weight gain). Bruising could be related to injury or altered liver function. Note any caput medusae or spider angiomas. Jaundice color may indicate liver or gallbladder disease.</td>
</tr>
<tr>
<td>Auscultation</td>
<td>Soft bowel sounds should be heard in all quadrants every 5–15 seconds. Circulatory sounds should be absent.</td>
<td>Hyperactive sounds are heard with increased motility such as diarrhea. Hypoactive sounds are associated with decreased motility such as abdominal surgery, paralytic ileus, or bowel obstruction. A humming sound may be heard over the liver in patients with chronic liver failure.</td>
</tr>
<tr>
<td>Percussion</td>
<td>Completed by health care provider.</td>
<td></td>
</tr>
<tr>
<td>Palpation</td>
<td>No pain, muscle tension, rigidity, or masses should be felt on light palpation. The abdomen should feel soft. Abdominal girth should be appropriate for patient without increasing. Deep palpation is done by the advanced practitioner.</td>
<td>Muscle tension, rigidity, or pain may occur in many abdominal disorders. Patients with ascites from liver disease may have an increased girth that increases as the disease worsens.</td>
</tr>
<tr>
<td>Anus</td>
<td>No lumps, rashes, scars, erythema, bleeding, fissures, or hemorrhoids.</td>
<td>Hemorrhoids may be present. Patients with diarrhea may have skin breakdown or rash.</td>
</tr>
</tbody>
</table>
Oral Cavity

GI assessment begins with the oral cavity. The lips are examined for lesions, abnormal color, and symmetry. With a penlight and tongue blade, the oral cavity is inspected for inflammation, tenderness, ulcers, swelling, bleeding, and discolorations. Any odor of the patient’s breath is noted. A foul odor may indicate infection or poor oral care. The tongue should be pink with a rough texture and assessed for signs of dehydration such as dryness, cracks, or furrows. The patient’s gums should be pink without swelling, redness, or irregularities. The teeth or dentures are examined for loose, broken, or absent teeth and the fit of the dentures or dental work. Ill-fitting dentures can affect the patient’s nutritional intake and obstruct the airway. Loose teeth can become dislodged and aspirated into the airway. Broken teeth can be a source of pain and contribute to poor nutritional intake.

The patient’s knowledge of dental and oral care is assessed. The ability of the patient to perform oral care is noted and included in the plan of care if there are deficits. Oral health is very important to a person’s overall health and well-being.

Abdomen

Be prepared to assist with a thorough physical assessment of the patient. Instead of following the usual inspect-palpate-percuss-auscultate (IPPA) format, assess the abdomen starting with inspection, then auscultation, percussion, and palpation. This is to prevent palpation from altering other assessment findings.

**INSPECTION.** To inspect the abdomen, patients are placed in a supine position with their arms at their sides. The abdomen is visually inspected to note the condition of the skin and the contour. The contour may be rounded, flat, concave, or distended, depending on the patient’s body type. Abdominal pulsatile masses are noted. Such masses may be visible in thin persons or they may indicate an abdominal aortic aneurysm. Irregularities in contour may be due to distention, tumors, hernia, or previous surgeries. Also note any wounds, tubes, or ostomy devices including type and location.

Inspect the patient’s skin for scars, striae (commonly called stretch marks; light silver-colored or thin red lines on the abdomen), bruising, caput medusae (bluish purple swollen vein pattern extending out from the navel), and spider angiomas (thin reddish purple vein lines close to the skin surface). Note any petechiae. The patient’s abdomen

**Findings**

- Below 18.5: underweight
- 18.5–24.9: normal
- 25–29.9: overweight
- 30 and over: obese

**To obtain waist measurement:**

- Step 1. Place measuring tape around bare waist at top of the iliac crest.
- Step 2. Pull snugly around the waist.
- Step 3. Read measurement at end expiration.

**To obtain waist-to-hip ratio measurement**

- Step 1. Place measuring tape at the level of the top of the iliac crest.
- Step 2. Pull snugly around the waist.
- Step 3. Read measurement at end expiration.
- Step 4. Place measuring tape around hip at widest part and read measurement.
- Step 5. Waist measurement is divided by hip measurement.

**Findings/risk for health complications:**

- Female: ≤ 0.8—low risk; > 0.85—high risk
- Male: ≤ 0.95—low risk; > 1.0—high risk

*Method for patients who are overweight or obese.

**Oral Cavity**

GI assessment begins with the oral cavity. The lips are examined for lesions, abnormal color, and symmetry. With a penlight and tongue blade, the oral cavity is inspected for inflammation, tenderness, ulcers, swelling, bleeding, and discolorations. Any odor of the patient’s breath is noted. A foul odor may indicate infection or poor oral care. The tongue should be pink with a rough texture and assessed for signs of dehydration such as dryness, cracks, or furrows. The patient’s gums should be pink without swelling, redness, or irregularities. The teeth or dentures are examined for loose, broken, or absent teeth and the fit of the dentures or dental work. Ill-fitting dentures can affect the patient’s nutritional intake and obstruct the airway. Loose teeth can become dislodged and aspirated into the airway. Broken teeth can be a source of pain and contribute to poor nutritional intake.

The patient’s knowledge of dental and oral care is assessed. The ability of the patient to perform oral care is noted and included in the plan of care if there are deficits. Oral health is very important to a person’s overall health and well-being.

**Abdomen**

Be prepared to assist with a thorough physical assessment of the patient. Instead of following the usual inspect-palpate-percuss-auscultate (IPPA) format, assess the abdomen starting with inspection, then auscultation, percussion, and palpation. This is to prevent palpation from altering other assessment findings.

**INSPECTION.** To inspect the abdomen, patients are placed in a supine position with their arms at their sides. The abdomen is visually inspected to note the condition of the skin and the contour. The contour may be rounded, flat, concave, or distended, depending on the patient’s body type. Abdominal pulsatile masses are noted. Such masses may be visible in thin persons or they may indicate an abdominal aortic aneurysm. Irregularities in contour may be due to distention, tumors, hernia, or previous surgeries. Also note any wounds, tubes, or ostomy devices including type and location.

Inspect the patient’s skin for scars, striae (commonly called stretch marks; light silver-colored or thin red lines on the abdomen), bruising, caput medusae (bluish purple swollen vein pattern extending out from the navel), and spider angiomas (thin reddish purple vein lines close to the skin surface). Note any petechiae. The patient’s abdomen

**Word Building**

**caput medusae:** caput—head + medusae—Medusa’s snaky locks
is observed for any visible masses, visible movement or peristalsis, or jaundice (also called icterus; a yellowing of the skin and the sclerae of the eyes).

Jaundice is a cardinal symptom of liver or gallbladder disease and red blood cell disorders. Old red blood cells are cleared from the circulatory system by phagocytes in the spleen, liver, lymph nodes, and bone marrow. In the process, the compound heme (part of hemoglobin) is split into iron and another substance that is metabolized to bilirubin. The liver is then responsible for converting bilirubin to a water-soluble compound that can be excreted in bile. If the liver is unable to convert or conjugate bilirubin to a water-soluble compound or if bile drainage is obstructed, serum bilirubin is elevated and pigments are deposited in body tissues.

When serum bilirubin levels elevate, the patient’s skin color changes to yellow. The yellow color varies from pale yellow to a striking golden orange. The color intensity is directly related to the amount of elevation of the serum bilirubin. Jaundice can be seen in nearly every body tissue and fluid where there is any amount of albumin (“Cultural Considerations”). Pigment may occasionally be seen in cerebrospinal fluid or joint fluid. Pigment is not seen in saliva or tears. Urine becomes dark, and if bile flows to the bowel is obstructed, stools will be a light clay color. Describe any abnormal finding completely in the patient’s record, and report your findings promptly.

The perianal and anal areas are inspected. Inspect the area for color, rashes, scars, fissures, external hemorrhoids, or skin breakdown. Describe any abnormal findings.

AUSCULTATION. When auscultating the patient’s abdomen, the upper right quadrant is auscultated first (Fig. 32.5). Then a clockwise direction is followed to listen to the other quadrants. The stethoscope is pressed lightly on the abdomen to listen for bowel sounds, which are soft clicks and gurgles that may be heard every 5 to 15 seconds, occurring irregularly 5 to 30 times per minute. Bowel sounds at this rate are considered normal.

Bowel sounds are produced when peristalsis moves air and fluid through the GI tract, and they are categorized as normal, hyperactive, hypoactive, or absent. Hyperactive bowel sounds are usually rapid, high pitched, and loud and may occur with hunger or gastroenteritis. Hypoactive bowel sounds are bowel sounds that are infrequent and can occur in patients with a paralytic ileus or following abdominal surgery (see “Evidence-Based Practice”). Bowel sounds are considered absent if no sounds are auscultated after listening to all four quadrants for 2 to 5 minutes in each quadrant. However, this timing is an area for further research because, in practice, auscultation for this amount of time is rarely done. With a bowel obstruction, a high-pitched tinkling sound that is proximal to the obstruction and absent distal to the obstruction may be heard. Abnormal or absent bowel sounds are important findings and should be documented and reported to the HCP.

Note the presence of any vascular sounds or bruits (swishing sounds), which are normally not present, are heard with the stethoscope over the aorta. Patients with chronic liver failure may have a humming sound over their liver. This finding usually indicates overloaded venous circulation in the liver.

PERCUSSION. Percussion produces a sound that identifies the density of the organs beneath the area being percussed and is performed by the HCP. Percussion is used to detect fluid, air, and masses in the abdomen and to identify size and location of abdominal or organs (especially the liver and spleen). Tympanic high-pitched sounds indicate the presence of air, and dull thuds indicate fluid or solid organs.

LEARNING TIP

In a complete bowel obstruction, air and fluid are propelled forward by peristalsis proximal to the obstruction. This produces proximal high-pitched bowel sounds when the air and fluid create turbulence as they hit the obstruction and are unable to pass. Absent bowel sounds are heard distal to the obstruction. If a patient has a nasogastric (NG) tube for suction, turn off the suction before listening for bowel sounds.

PALPATION. Light palpation of the abdomen concludes the physical assessment. If the patient is having pain, that area should be palpated last. Using the same quadrant approach as previously mentioned (see Fig. 32.5), lightly depress the abdomen not more than 0.5 to 1.0 inch during the palpation using the finger pads. Note any muscle tension, rigidity, masses, or expressions of pain.

Deep palpation of the abdomen is done only by the HCP. Rebound tenderness is determined by pressing down on the abdomen a few inches and quickly releasing the pressure. If the patient feels a sharp pain during this procedure, appendicitis may be indicated.

• WORD • BUILDING •
jaundice: jaune—yellow

Cultural Considerations

The nurse should be aware of the variations among people of color when assessing for jaundice. To assess for jaundice in a patient with dark skin, look at the sclerae, conjunctivae, palms of hands, soles of feet, and in the buccal mucosa for patches of bilirubin pigment.
Abdominal girth is measured by placing a tape measure around the patient’s abdomen at the iliac crest. A mark is made at the measurement site so measurements are made at the same location for comparison. Abdominal girth is increased in patients with distention or conditions such as ascites (accumulation of fluid in the peritoneal cavity). When abdominal girth is abnormal, daily measurements should be obtained and recorded to monitor changes.

**DIAGNOSTIC TESTS FOR THE GASTROINTESTINAL, HEPATOBILIARY, AND PANCREATIC SYSTEMS**

See Appendix B for general information on common diagnostic tests.

**Laboratory Tests**

The complete blood cell count (CBC) reveals if anemia or infection is present. Anemia may occur with GI bleeding or cancer. Electrolyte imbalances often occur with GI illness as a result of vomiting, diarrhea, malabsorption, or use of GI suction. Carcinoembryonic antigen and carbohydrate antigen 19-9 are markers used to monitor GI cancer treatment effectiveness and detect recurrence (Tables 32.6 and 32.7). These markers are also found in patients with cirrhosis, hepatic disease, and alcoholic pancreatitis and in heavy smokers. Genetic testing can be done to identify family members at risk of developing serious conditions such as the polyps associated with colon cancer.

Bilirubin level is an excellent measure of liver and gallbladder functioning. In addition, certain enzymes such as alanine aminotransferase, aspartate aminotransferase, and lactic dehydrogenase are released by damaged liver cells. Elevations in these blood values in the absence of known trauma or heart muscle damage such as a heart attack are excellent indicators of liver damage.

**Stool Tests**

Stool samples can be tested for occult blood (blood not seen by the naked eye). A series of three tests is usually done to increase the chances of detecting blood. False-positive occult blood results can occur with bleeding gums following a dental procedure; ingestion of red meat within 3 days before testing; ingestion of fish, turnips, or horseradish; and use of drugs, including anticoagulants, aspirin, colchicine, iron preparations in large doses, NSAIDs, and steroids.

---

**Evidence-Based Practice**

*Clinical Question*

Can gum chewing reduce the incidence of postoperative ileus?

*Evidence*

A meta-analysis of four studies of early gum chewing after surgery demonstrated that there can be a reduction time in the first flatus after surgery by 12 hours, reduction of time in the first bowel movement by 1 day, and a decreased length of hospital stay by 1 day.

*Implications for Nursing Practice*

Early gum chewing after surgery can reduce time of flatus after surgery, decrease time of first bowel movement, and length of hospital stay by 1 day. Patients should chew sugarless gum three or four times a day for 5 to 30 minutes, unless not tolerated.

</table>
Stool is collected to detect intestinal infections caused by parasites and their ova (eggs). The test usually requires a series of three stool specimens collected every second or third day. The stool specimen is collected using a tongue blade, placed in a container with a preservative, and sent immediately to the laboratory. The stool must be examined within 30 minutes of collection. False-negative results can occur as a result of urine in the specimen or if the specimen is not fresh.

Stool cultures (sterile collection technique) are done to determine the presence of pathogenic organisms in the GI tract. Stool can also be examined for lipids (fat). Excessive secretion of fecal fats (steatorrhea) may occur in various digestive and absorptive disorders. The stools are collected for 72 hours and stored on ice if necessary before being sent to the laboratory.

**Radiographic Tests**

**Upper Gastrointestinal Series (Barium Swallow)**

An upper gastrointestinal (GI) series is an x-ray examination of the esophagus, stomach, duodenum, and jejunum using an oral liquid radiopaque contrast medium (barium) and a fluoroscope (an x-ray source and fluorescent screen between which the patient is placed) to outline the contours of the organs. An upper GI series is used to detect such things as strictures, ulcers, tumors, polyps, hiatal hernias, and motility problems.

The patient receives nothing by mouth (NPO) for 6 to 8 hours before the procedure. Usually the patient has a clear liquid supper the night before the procedure and is then NPO until the procedure is done. Because smoking can stimulate gastric motility, the patient is discouraged from smoking the morning of the procedure. Patient teaching includes information about the patient’s diet before and after the procedure, the barium ingestion, and the appearance of stools afterward. During the procedure, the patient drinks thick, chalky barium while standing in front of a fluoroscopic tube. X-ray films are taken in various positions and at specific intervals to visualize the outline of the organs and to note the passage of the barium through the GI tract. The patient should understand that the procedure may take several hours depending on the rate at which the barium moves through the patient’s GI tract.

A laxative is usually ordered after the procedure to expel the barium and prevent constipation or a barium impaction (impassable mass of stonelike feces). The patient is instructed to drink 12 eight-ounce glasses of water per day for several days to prevent dehydration, which can lead to constipation. The abdomen is assessed for distention and bowel sounds. The stool is monitored to determine whether the barium has been completely eliminated. Initially, the barium causes the patient’s stool to be white, but it should return to its normal color within 3 days. Constipation with distention indicates a barium impaction.

**Lower Gastrointestinal Series**

The lower GI series (barium enema) is performed to visualize the position, movements, and filling of the colon. Tumors, diverticula, stenosis, obstructions, inflammation, ulcerative colitis, and polyps can be detected. The patient is placed on a low-residue or clear liquid diet for 2 to 5 days before the test to empty the bowel. Laxatives, bowel-cleansing solutions and enemas may be administered the

**WORD BUILDING**

steatorrhea: steato—fat + rrhea—flow
fluoroscope: fluor—a flowing + skopeîn—to look at
GoLYTELY is chilled and drunk full strength with no ice, 8 ounces every 10 minutes for a total of 4 L. Drinking this solution can be unpleasant for the patient. Inform the patient that a watery diarrhea will begin in about 1 hour and continue for up to 5 hours as the bowel is cleared. Other bowel preparations are available such as sodium picosulfate/magnesium oxide/anhydrous citric acid or polyethylene glycol (Miralax). Bowel preparation is necessary for adequate visualization during the procedure. Inadequate bowel preparation may result in poor test results or test cancellation (Fig. 32.6). The patient either receives a clear liquid diet the morning of the test up to 2 to 4 hours before the test or is NPO after midnight the night before. The area around the rectum should be clean before the patient is sent for the procedure. If the patient has active inflammatory disease of the colon or suspected perforation or obstruction, a barium enema is contraindicated. Active GI bleeding may also prohibit the use of laxatives and enemas.

During the procedure, barium is instilled rectally and x-ray films are taken with or without fluoroscopy. The patient may experience some abdominal cramping and an urge to have a bowel movement during the procedure. The patient is told to take slow, deep breaths and to tighten the anal sphincter. The rate of flow of the barium is slowed until the cramping diminishes. The procedure takes about 15 minutes, and the patient is allowed to use the bathroom immediately after the procedure.

The patient’s stools are monitored after the procedure to note if all the barium is passed, as with the UGI series. Constipation development is monitored. The patient is encouraged to drink at least one 8-ounce glass of liquid per hour for the next 24 waking hours to help remove the barium. Laxatives may be ordered to help clear the barium from the colon. The patient is told to report any abdominal pain, bloating, or absence of stool, all of which could indicate constipation or bowel obstruction, as well as any rectal bleeding.

CRITICAL THINKING

Mrs. Pearl

Mrs. Pearl is a 95-year-old woman undergoing a lower GI series for abdominal pain. As her nurse, what concerns might you have for Mrs. Pearl as she undergoes this test? How can you address them?

Nuclear Scanning

Nuclear scanning of the gallbladder involves injecting a patient with a small amount of radioactive isotope. The scan is called a cholescintigraphy, DISIDA, HIDA, or PIPIDA scan, depending on the radioactive isotope and exact procedure that is used. A patient may be given a fatty meal or cholecystokinin to stimulate emptying of the gallbladder. Any biliary disease, ejection problem, or obstruction can be confirmed with this examination.

Liver Scan

A liver scan involves injecting a slightly radioactive medium that is taken up by the liver. An instrument is passed over the liver that records the amount of material taken up by the liver and forms a composite picture of the liver. The HCP may be able to determine tumors, masses, and abnormal size and patterns of blood vessels. The procedure takes a short time.
Endoscopy

Esophagastroduodenoscopy

Esophagastroduodenoscopy (EGD) visualizes the esophagus (esophagoscopy), the stomach (gastroscopy), and the duodenum (Fig. 32.7). Conscious sedation, for example, midazolam (Versed), is used to relax and ease pain during the procedure. Sometimes a local anesthetic in spray or gargle form is given to inhibit the gag reflex. Abnormalities such as inflammation, cancer, bleeding, injury, and infection can be seen. Biopsy or cytology specimens can be obtained.

After the procedure, vital signs are monitored. If the patient had a local anesthetic for the throat, keep patient NPO and check for gag reflex return before allowing fluids or food (usually within 4 hours). Patients are assessed for signs of perforation, which include bleeding, fever, and dysphagia. Midesophageal perforation can cause referred substernal or epigastric pain. Blood loss secondary to perforation can lead to cyanosis and referred back pain. Distal esophageal perforation may result in shoulder pain, dyspnea, or symptoms similar to those of a perforated ulcer. The patient may have a sore throat for a few days.

Capsule endoscopy makes use of a capsule with a microchip in it that is swallowed. As the capsule moves through the GI tract, pictures are taken of the stomach and small intestine to diagnose conditions such as bleeding, tumors, or Crohn’s disease. It is most helpful in the small intestine, which is difficult to scope because of its length and twists. Advances in this technology are focusing on the power supply and performing treatments as with an endoscope.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) permits the HCP to visualize the liver, gallbladder, and pancreas (Fig. 32.8). The procedure allows both direct viewing and use of contrast medium and intervention if needed such as biopsy, stone or tumor removal, stricture balloon dilation, or bile duct stent placement. An endoscope is passed through the esophagus to the duodenum, where dye is injected that outlines the pancreatic and bile ducts.

The patient is prepared for an ERCP in the same manner as for an EGD. NPO times can vary (8–12 hours) before the procedure. In addition, the patient is asked about allergies to contrast agents. Ensure that any ordered laboratory studies have been done before the procedure and that the patient has removed dentures. Postprocedure pancreatitis can develop. A pancreatic stent may be placed to help prevent this in certain patients. Follow-up care is similar to that for an EGD. In addition, the nurse is alert to patient reports of increased right upper quadrant pain, fever, or chills, which may indicate infection. Hypotension, tachycardia or rapid heart rate, increasing RUQ pain, nausea, or vomiting may indicate perforation or the onset of pancreatitis. Report such findings immediately.

Lower Gastrointestinal Endoscopy

Proctosigmoidoscopy. Proctosigmoidoscopy is the examination of the distal sigmoid colon, the rectum, and the anal canal using a flexible endoscope (sigmoidoscope). Ulcerations, punctures, lacerations, tumors, hemorrhoids, polyps, fissures, fistulas, and abscesses can be detected. Malignancies at an early stage can be detected, so an examination for patients age 50 and older is recommended every 5 years.

Proctosigmoidoscopy requires the lower bowel to be cleaned out. The patient usually receives a clear liquid diet 24 hours before the test and a laxative the night before the test. The morning of the procedure a warm tap-water enema, or sodium phosphate (Fleet) enema may be given. Bowel preparation may not be ordered for patients with bleeding or severe diarrhea.

The patient is positioned in a left lateral knee-to-chest position, which allows the sigmoid colon to straighten by gravity. A rigid proctoscope is used to visualize the rectum. A flexible scope is then used to permit visualization above the rectosigmoid junction. Patients are told they may feel pressure as though they are going to have a bowel movement.
During the procedure, one or more small pieces of intestinal tissue may be removed (biopsy specimens). Rectal or sigmoid polyps are removed with a snare. An electrocoagulating current is used to cauterize sites to prevent or stop bleeding. Specimens are labeled and sent to the pathology laboratory immediately for examination.

After the procedure, the patient is allowed to rest for a few minutes in the supine position to avoid orthostatic hypotension when standing. Pain and flatus may occur from instilled air. The patient is observed for signs of perforation such as bleeding, pain, and fever.

**Colonoscopy.** Colonoscopy provides visualization of the lining of the large intestine to identify abnormalities through a flexible endoscope, which is inserted rectally. A biopsy specimen may be obtained or polyps removed during the colonoscopy.

The patient receives a clear liquid diet 24 hours before the test and is NPO after midnight before the procedure. A bowel preparation solution is given the night before the procedure such as bisacodyl [Dulcolax], or enema. Bowel preparations similar to lower GI series can be used.

**BE SAFE!**

Older patients may experience fatigue and weakness during bowel preparation and may be unable to complete it. Monitor the patient for distress. Consult the HCP if you note any patient distress during bowel preparation. Observe the patient often because defecation urgency, especially in unfamiliar surroundings, may create a fall risk.

Conscious sedation is used. The patient is positioned on the left side with the knees bent. A small amount of air is instilled into the colon to help the HCP visualize the bowel. The air causes pressure and may be uncomfortable for the patient. The patient is encouraged to relax and take slow deep breaths through the nose and out the mouth. Vital signs are monitored throughout the procedure to watch for a vasovagal response, which can lead to hypotension and bradycardia.

After the procedure, the patient is monitored until stable. Complications such as hemorrhage or severe pain are reported. When giving the patient discharge instructions, explain that flatus and cramping will occur for several hours after the test, that blood may be present in the stool if a biopsy specimen was taken, and to report problems to the HCP.

**Gastric Analysis**

**Gastric analysis** measures the secretions in the stomach. Diagnoses of duodenal ulcer, gastric carcinoma, pyloric or duodenal obstruction, and pernicious anemia are made with this test. A diagnosis of pernicious anemia is ruled out by the finding of acid. A diagnosis of gastric carcinoma may be made by the presence of cancer cells in the gastric secretions. The two gastric analysis tests performed are the basal cell secretion test and the gastric acid stimulation test.

Before the basal cell secretion test, the patient should not be taking any drugs that could interfere with gastric acid secretion, such as cholinergics and antacids. The patient is NPO after midnight the night before the test. For the procedure, a NG tube is inserted and the contents of the stomach are suctioned out through the tube using a syringe. The NG tube is connected to wall suction, and stomach contents are collected every 15 minutes for 1 hour. The specimens are labeled according to the time they were collected and the order in which they were obtained. The gastric acid is tested for pH using indicator paper or a pH meter. The amount of gastric acid is also measured. Too much hydrochloric acid may indicate a peptic ulcer; too little could be a sign of cancer or pernicious anemia.

The gastric acid stimulation test measures the amount of gastric acid for 1 hour after subcutaneous injection of a histamine drug. If abnormal results occur, radiographic tests or endoscopy can be done to determine the cause.

**Percutaneous Liver Biopsy**

If less invasive tests do not aid in diagnosis of liver disease, a liver biopsy can be done. This type of biopsy can identify cancer, cirrhosis, hepatitis, or other causes of liver disease. The HCP generally inserts a needle through the skin and into the liver to withdraw a small sample for examination. This procedure places the patient at risk for bleeding because the liver is highly vascular and because many patients with liver disease have reduced clotting ability.

During the procedure the nurse assists the HCP to position the patient on his or her back or left side and assists the patient to hold very still while the needle is being introduced. The HCP may also ask the patient to exhale and hold his or her breath during the needle insertion.

After the biopsy, the patient should remain on bed rest for 24 hours. The patient lies on the right side for the first 2 hours with a small pillow or rolled towel under the biopsy site to provide pressure and prevent bleeding. Vital signs and the site are monitored for signs of bleeding. The patient is advised to avoid coughing or straining. Analgesics are offered for comfort if ordered.

See Table 32.8 for a summary of diagnostic procedures for the GI system.

**CRITICAL THINKING**

**Mr. Wozynski**

- Mr. Wozynski is admitted with chronic liver failure and jaundice. What specific laboratory value can you expect to be elevated related to his jaundice? Mr. Wozynski’s HCP orders a liver biopsy. Why is it important for you to check Mr. Wozynski’s laboratory reports before the procedure? **Suggested answers are at the end of the chapter.**

**Gastrointestinal Intubation**

GI intubation is the placement of a tube within the GI tract for therapeutic or diagnostic purposes (Fig. 32.9). When the GI tube is inserted orally into the stomach it is an orogastric tube. When it goes from the nares into the stomach, it is referred to as a nasogastric tube. A variety of tubes are available, each designed for specific purposes (Table 32.9). Orogastric tubes reduce sinus infection risk because they do not block normal drainage of the sinuses, as can nasal tubes.

GI intubation is done for a variety of reasons:
- To remove gas and fluids from the stomach (decompression)
- To diagnose GI motility and to obtain gastric secretions for analysis
- To relieve and treat obstructions or bleeding within the GI tract
- To provide a means for nutrition (gavage feeding), hydration, and medication when the oral route is not possible or is contraindicated
- To promote healing after esophageal, gastric, or intestinal surgery by preventing distention of the GI tract and strain on the suture lines
- To remove toxic substances (lavage) that have been ingested either accidentally or intentionally and to provide for irrigation.

**Enteral Nutrition**

Enteral nutrition supplies patients with nutrition when oral intake is not possible. Feedings can be given to the patient as a supplement or to provide the patient’s total nutritional needs. Enteral feedings are delivered directly into the duodenum or proximal jejunum. Patients may benefit from enteral nutrition to supplement their diet, support healing, or replace food and fluids when they cannot eat orally.

**Therapeutic Measures for the Gastrointestinal, Hepatobiliary, and Pancreatic Systems**

</tr>
</tbody>
</table>
from either oral or enteral nutrition within 24 hours postoperatively from GI surgery. Complications associated with enteral nutrition are presented in Table 32.10.

**Enteral Nutrition Formulas**

Enteral nutrition formulas are prescribed by the HCP based on the patient’s nutritional needs, the consistency of the formula, the size and location of the tube, the method of delivery, and the convenience for the patient at home. Commercially prepared formulas are composed of protein, carbohydrates, and fats. When patients receive enteral nutrition, their daily water needs in addition to any water supplied by the feeding should be considered. Dietitians can help calculate the patient’s free water needs. The water used to flush the tube or administer medications can be considered as meeting part of the patient’s daily total water needs. Dehydration can occur if the patient’s water needs are not met.

**Method of Enteral Feeding Delivery**

Feedings are administered either by gravity or by a controlled pump that delivers continuous volume through the feeding tube. Gravity feedings are placed above the level of the stomach and dripped in by gravity slowly or given as a bolus feeding over a few minutes. Intermittent feedings are defined as either being delivered by a pump that runs continuously throughout the day and is discontinued each night or as a 4- to 6-hour volume of feeding given over 20 to 30 minutes. Intermittent feedings via a pump allow the stomach to rest at night and more closely simulate normal eating and nutrient absorption patterns. A continuous feeding administered 24 hours a day through a pump allows for small amounts to be given over a long period. Pumps are set at the specified rate to control the speed of the feeding being delivered to the patient.

When feedings are administered, patients must be positioned in a sitting or high-Fowler’s position to reduce the risk...
**TABLE 32.9 GASTRIC TUBES**

<table>
<thead>
<tr>
<th>Tube</th>
<th>Uses and Description</th>
<th>Nursing Considerations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Levin tube</td>
<td>Single lumen. May be used for gastric decompression, irrigation, lavage, and feeding.</td>
<td>Tube is not vented. Avoid use with continuous suction to prevent injury to stomach lining.</td>
</tr>
<tr>
<td>Salem sump tube</td>
<td>Double lumen, “pigtail” acts as an air vent and prevents excess suction, which could damage stomach lining. Air vent must not be plugged off. Used for decompression, irrigations, and lavage.</td>
<td>May be used with continuous suction because of air vent.</td>
</tr>
<tr>
<td>Weighted, flexible feeding tubes with stylets</td>
<td>Small-bore tube for enteral feeding only. Less injury. Remains in place for extended periods.</td>
<td>Suction collapses tube. Use 10-mL syringe or greater because smaller syringe creates too much pressure, possible rupture of tube. Inject 30 mL of air with a 60-mL syringe immediately before withdrawing fluid to make it easier to withdraw.</td>

</tbody>
</table>

*Note: NPO = nothing by mouth.*

**TABLE 32.10 COMMON MECHANICAL, GASTROINTESTINAL, AND METABOLIC COMPLICATIONS OF TUBE-FED PATIENTS AND PREVENTION STRATEGIES**

<table>
<thead>
<tr>
<th>Complication</th>
<th>Prevention Strategies</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Mechanical</strong></td>
<td></td>
</tr>
<tr>
<td>Tube irritation</td>
<td>Consider oral tubes and avoid nasal tubes due to sinus infection risk. Oral tubes also help prevent ventilator-associated pneumonia. Consider using a smaller or softer tube. Lubricate tube before insertion. Make sure tube is secured in place.</td>
</tr>
<tr>
<td>Tube obstruction</td>
<td>Flush tube with water after each use and before and after medication administration. Do not mix medications with tube-feeding formula. Use liquid medications if available. Crush other medications thoroughly (if not contraindicated). Use infusion pump to maintain constant flow (see Fig. 32.9).</td>
</tr>
<tr>
<td>Aspiration and regurgitation</td>
<td>Feeding should not be started until tube placement is radiographically confirmed. Avoid use of blue dye to detect aspiration because it has not been shown predictive, and dye can be absorbed in critically ill patients, who then turn blue and can die. Elevate head of patient’s bed 30 degrees or more at all times. Discontinue feeding at least 30–60 minutes before treatments requiring head to be lowered (e.g., chest percussion). If patient has an endotracheal tube in place, keep cuff inflated during feeding.</td>
</tr>
<tr>
<td>Tube displacement</td>
<td>Place a black mark at the point where tube, when properly placed, exits the nostril. Measure exposed length for future placement verification. Replace tube and obtain HCP’s order to confirm with x-ray imaging.</td>
</tr>
</tbody>
</table>

*Continued*
of aspiration. Monitor the rate carefully to avoid administering feedings too rapidly, and watch for signs that the feeding is not being absorbed. Abdominal distention, patient report of a feeling of fullness, and nausea or vomiting are indicators that the feeding is not being absorbed and should be stopped to prevent aspiration. A residual check to see how much feeding, if any, has not been absorbed is done hourly when the feeding is initiated, then every 4 hours or before giving any medications or adding more feeding for infusion. If there is more than 100 mL or the amount specified by the agency or HCP, the feeding should be stopped to prevent vomiting or aspiration and the HCP notified. Continuous or intermittent feedings reduce the risk of aspiration, distention, nausea, vomiting, and diarrhea.

*The most commonly cited complication of enteral feeding is diarrhea.*
If medications are administered during enteral feeding, understand possible drug–nutrient interactions. Some medications cannot be given with certain substances. Other medications, such as enteric-coated or sustained-release medications, should not be crushed. Liquid medications should be used when possible to reduce clogging of the tube. Pharmacists and dietitians should be consulted for special considerations.

**Gastrointestinal Decompression**

GI decompression may be necessary when the stomach or small intestine becomes filled with air or fluid. Swallowed air and GI secretions enter the stomach and intestines and collect there if they are not propelled through the GI tract by peristalsis. Accumulating air or fluid causes distention, a feeling of fullness, and possibly pain in the abdomen. Gastric distention may occur after major abdominal surgery. Ambulating or turning the patient frequently can help prevent this. However, when GI decompression is necessary, a NG tube or occasionally a nasointestinal tube may be inserted and suction applied. Nasointestinal tubes are more difficult and slower to place and may be uncomfortable, so they are not used often. The tube remains in place until full peristaltic activity (active bowel sounds and passage of flatus) has returned. The diet is then progressed as ordered and tolerated by the patient.

**Parenteral Nutrition**

Parenteral nutrition (PN) is a method of supplying nutrients to the patient by a central or peripheral IV route. PN solutions usually contain dextrose (sugar), amino acids (protein), vitamins, minerals, and fat (intralipid) emulsions. PN solutions are designed to improve the patient’s nutritional status, achieve weight gain, and enhance the healing process. Patients with conditions such as burns, trauma, cancer, acquired immunodeficiency syndrome (AIDS), malnutrition, anorexia nervosa, or fever and those undergoing major surgery may need PN.

**BE SAFE!**

Incorrect connection of enteral feeding equipment is a hazard to patient safety. An enteral feeding incorrectly connected and administered through a nonenteral system (such as an IV line, peritoneal dialysis catheter, oxygen tubing, or tracheostomy tube cuff) can result in patient injury or death. Luer connections require extra caution. Equipment redesigns have been undertaken to make these types of faulty connections less possible. Nurses must be vigilant to ensure that they understand the appropriate use of the equipment and all tubing connections being made to prevent harmful errors:

- Avoid rigging connections that may impair designed safety features.
- Package together all parts needed for enteral feeding within the agency to avoid improper equipment being selected and connected.
- Label or color-code feeding tubes and connectors within the institution.
- Verify the solution’s label (a 3-in-1 parenteral nutrition solution looks similar to enteral nutrition).

**CRITICAL THINKING**

**Mrs. Wood**

Mrs. Wood is receiving enteral nutrition because of dysphagia, the cause of which is being investigated. Mrs. Wood is not receiving any medications. You note that Mrs. Wood’s tongue is bright red with deep furrows. She states her mouth is very dry. Her skin remains tented when skin turgor is checked.

1. What do Mrs. Wood’s data collection findings indicate?
2. How would you document your findings?
3. What other data should you gather?
4. Why might Mrs. Wood be exhibiting this condition?
5. What actions could you take for this condition?
6. How would you record the total of Mrs. Wood’s 8-hour intake, which is an enteral feeding at 50 mL per hour?

_Suggested answers are at the end of the chapter._
Peripheral Parenteral Nutrition

Peripheral parenteral nutrition (PPN) is a method of supplying nutrients to the patient by an IV route that is not a central vein. PPN is used for less than 10 days when the patient does not need more than 2000 calories daily. PPN solutions can contain a mixture of dextrose (of less than 12%), amino acids, and lipids, in addition to electrolytes or water, which can be found in routine IV solutions. The all-in-one PPN system mixes dextrose, amino acids, and lipids all in one container, which causes less vein irritation.

NURSING CARE TIP

Patients with any of the following may need to be considered for PPN:
- Any significant weight loss (10% or more of healthy weight)
- A decrease of oral food intake for more than 3 days
- Any significant sign of protein loss: serum albumin levels below 3.2 g/dL
- Muscle wasting
- Decreased tissue healing
- Persistent vomiting and diarrhea.

Usually, RNs are responsible for administering PPN. A filter might be required with PPN solutions and possibly lipid solutions. It is important to monitor glucose levels as ordered and to look for signs of hyperglycemia in the patient receiving PPN. Refer to agency policy for obtaining glucose levels when a hyperglycemic reaction is suspected in the patient receiving PPN.

During PPN administration, the following laboratory values, as ordered, are usually monitored:
- CBC
- Albumin
- Glucose
- Electrolytes
- Platelet count
- PT

PN can be irritating to the peripheral veins because it is five or six times more concentrated than blood. Therefore, PPN dextrose more than 12% is administered through a central venous catheter into a large vein such as the subclavian or internal jugular (see Fig. 7.7). The volume in the large vein dilutes the PN solution, so it is less irritating.

LEARNING TIP

- Patients may respond to PN with an elevated serum glucose level, even though they do not have diabetes. This is due to the high concentration of glucose used in PN. These elevated serum glucose levels do not usually indicate that the patient who does not have diabetes has acquired the disease. After the PN is discontinued, the serum glucose levels should return to baseline or normal levels.
- Regular insulin is given, as ordered, to control hyperglycemia during PN therapy. The insulin is ordered on a sliding scale (regular insulin given based on blood glucose levels measured at ordered intervals over 24 hours) or as an additive to the PN solution, or both.
- Administration of insulin according to a sliding scale requires a current blood glucose level. Based on the obtained glucose level, if it is elevated, specified regular insulin units may be ordered. Usually blood glucose is measured before meals, but for a patient who is not eating, as with most patients receiving PN, there is no mealtime. Instead, specified time intervals are ordered (typically every 6 hours).
- Insulin given on a sliding scale is always regular insulin. Can you figure out why? Regular insulin is rapid acting, which is what is needed to treat the current blood glucose level that was obtained to determine what insulin coverage was needed, if any.

Home Health Hints

- Be familiar with community nutritional support services: the Women, Infants, and Children (WIC) program, nutrition sites for older adults, Meals on Wheels, school food programs, and government surplus food programs.
- Observe patient’s food preparation facilities to ensure the patient’s nutritional needs can be met. Some older patients may have outdated or spoiled food in their refrigerators or cupboards because they are unable to see dates or mold growing on foods.
- Ensure that patients are able to use appliances to heat food safely. Patients with limited vision may not see gas flames and can ignite their clothing. Confused patients might try to heat foods in
cardboard containers. If the patient is able to obtain and learn to use a microwave, it may be a safer cooking appliance than a stove.

- A feeding tube can be prevented from kinking by slipping a split straw lengthwise around the area that tends to kink and lightly taping over the split in the straw.
- Wire coat hangers make good hooks for enteral feeding solution bags. They can be bent and hung over doorways or closet bars.

CRITICAL THINKING

Mrs. Todd
1. Daily aspirin use is the most likely cause of her bleeding.
2. Medication teaching including side effects can help Mrs. Todd prevent future bleeding episodes. Mrs. Todd should be instructed to take aspirin with food to minimize GI upset and help prevent formation of ulcers. Assessment of pain relief needs and consultation with the HCP will also help.
3. See Table 32.8.

Mrs. Pearl
Mrs. Pearl is at risk for dehydration and electrolyte loss as a result of the laxative and enema preparation and NPO status. This risk is increased because of her age. Her fluid and electrolyte status should be monitored closely.

Mrs. Pearl will likely have a concern about “making it” to the bathroom during the preparation and should have a bedside commode placed within easy reach. Her call light should be answered promptly. If enemas are ordered “until clear,” Mrs. Pearl will be at greater risk for fluid and electrolyte loss. If more than two or three enemas are required, the HCP should be notified.

Older patients can become very fatigued during testing and test preparation. Mrs. Pearl should be allowed plenty of rest before and after the test. She may also have a concern about being able to hold the barium in her bowel during the test without having an “accident.” She should be assured that the barium is held in with a balloon that is on the end of the enema catheter and that bathrooms are nearby.

Mr. Wozynski
You can expect to find that Mr. Wozynski’s serum bilirubin is elevated because his liver is unable to convert or conjugate bilirubin into a water-soluble compound that can be eliminated in feces. Mr. Wozynski is at risk for bleeding because the liver is highly vascular and prone to bleed when a biopsy specimen is taken. In addition, he may not be manufacturing the necessary amount of prothrombin needed for blood clotting and is less likely to stop bleeding once the biopsy has been performed. It will be especially important to check his coagulation studies and report any elevations to the HCP before the biopsy.

Mrs. Wood
1. Assessment of Mrs. Wood indicates dehydration.
2. Document as follows: “0800 ‘Mouth very dry.’ Tongue bright red with deep furrows, tented turgor. Enteral feeding infusing (include solution and rate). Physician notified. K. Ohno, LVN.”
3. You would assess Mrs. Wood’s vital sign to look for changes such as increased heart rate, decreased blood pressure, and possibly mildly elevated temperature. The nurse would review current lab work if available for indications of dehydration such as elevated blood urea nitrogen (BUN) and elevated hematocrit (see Chapter 6).
4. Mrs. Wood’s daily water needs are not being met. She is not receiving medications that would incidentally provide water during their administration.
5. Consult a dietitian and/or HCP to review Mrs. Wood’s daily water needs. Divide the water needs over 24 hours and ensure that water is administered. Ensure tubing is flushed per agency policy, and calculate water used toward daily water needs. Monitor intake and output. Continue assessing Mrs. Wood’s signs and symptoms, and report abnormal findings.
6. 50 mL × 8 hours = 400 mL.
REVIEW QUESTIONS

1. The nurse is collecting data on a patient with a ruptured appendix that is painful. Where would the nurse expect the patient’s pain to be located?
   1. Right upper quadrant
   2. Right lower quadrant
   3. Left upper quadrant
   4. Left lower quadrant

2. The nurse is contributing to the plan of care for a 78-year-old patient’s elimination needs. Which of the following interventions should the nurse recommend to reduce complications from the aging change of slowed motility?
   1. Decrease ambulation.
   2. Decrease fluid intake.
   3. Increase dairy products.
   4. Increase dietary fiber.

3. The nurse is listening to a patient’s bowel sounds and hears them at an irregular rate every 5 to 15 seconds. How should the nurse document the findings?
   1. Normal bowel sounds heard every 5 to 15 seconds
   2. Hyperactive bowel sounds heard every 5 to 15 seconds
   3. Hypoactive bowel sounds heard every 5 to 15 seconds
   4. Abnormal bowel sounds heard every 5 to 15 seconds

4. Which of the following best describes the technique of palpation?
   1. Firmly place hands on abdomen, depressing tissues 1 to 2 inches.
   2. Randomly feel the patient’s abdomen with fingertips.
   3. Lightly depress the abdomen 0.5 to 1 inch.
   4. Light palpation is completed by an experienced practitioner.

5. The nurse is contributing to the plan of care for a patient who is to have a lower GI series. Which of the following measures should the nurse recommend be included in the plan of care?
   1. Have the patient cough and deep breathe hourly while awake.
   2. Encourage fluids.
   3. Check for return of a gag reflex.
   4. Keep the patient in semi-Fowler’s position.

6. A patient is admitted with an order for a sump tube (Salem sump). The nurse knows this tube is used for which of the following purposes? Select all that apply.
   1. Supplemental feeding
   2. Decompression
   3. Irrigation
   4. Lavage
   5. Gavage
   6. Parenteral nutrition

7. The nurse assisted with the insertion of a flexible feeding tube into a patient. Which of the following actions should the nurse take to confirm tube placement?
   1. Aspirate gastric contents for green-colored fluid.
   2. Measure the pH of secretions from tube.
   3. Obtain x-ray to check placement.
   4. Look in the back of the mouth for a coiled tube.

8. The nurse is caring for a patient who is receiving a PN infusion. The nurse would perform blood glucose monitoring every 6 hours to detect which complication?
   1. Hyponatremia
   2. Hyperkalemia
   3. Hypocalcemia
   4. Hyperglycemia

Answers can be found in Appendix C.
Nursing Care of Patients With Upper Gastrointestinal Disorders

LAZETTE V. NOWICKI

LEARNING OUTCOMES

1. Explain nausea, vomiting, anorexia, anorexia nervosa, and bulimia nervosa.
2. Describe therapeutic measures and nursing care for nausea, vomiting, anorexia, anorexia nervosa, and bulimia nervosa.
3. Describe medical, surgical, and nursing management for obesity.
4. Plan nursing care for a patient with stomatitis.
5. Plan nursing care for patients with acute or chronic gastritis.
6. Explain the pathophysiology, signs and symptoms, and diagnostic testing for hiatal hernia, peptic ulcer disease, gastric bleeding, and gastric cancer.
7. List current pharmacological treatments used for peptic ulcer disease.

KEY TERMS

- anorexia (AN-uh-REK-see-ah)
- anorexia nervosa (AN-uh-REK-see-ah nur-VOH-sah)
- aphthous stomatitis (AF-thus STOH-mah-TY-tiss)
- bariatric (BEAR-ry-AT-trick)
- bulimia nervosa (buh-LEE-mee-ah ner-VOH-sah)
- gastrectomy (gast-TREK-tuh-mee)
- gastritis (gas-TRY-tiss)
- gastroduodenostomy (GAS-troh-DOO-den-AW-stuh-mee)
- gastrojejunostomy (GAS-troh-JEE-joo-NAW-stuh-mee)
- Helicobacter pylori (HEH-lih-koh-back-tur PIH-loe-ree)
- hiatal hernia (hy-YAY-tuh! HER-nee-ah)
- obesity (oh-BEE-sih-tee)
- peptic ulcer disease (PEP-tick UL-sir dih-ZEEZ)
- Roux-en-Y (roo-ehn-WHY)
- steatorrhea (STEE-ah-toh-REE-ah)
- stomatitis (STOH-mah-TY-tiss)
NAUSEA AND VOMITING

Nausea is the subjective feeling of the urge to vomit. Vomiting is the act of expelling stomach contents from the body through the esophagus and mouth. It is a protective function to rid the body of harmful substances from the gastrointestinal (GI) tract. This reflex is controlled by the vomiting center of the brain. Stimuli and conditions that are directly related to the GI tract or independent of it can trigger nausea and vomiting. Viral GI infection and other infections, motion sickness, stress, pregnancy, medications (narcotics), myocardial infarction, uremia, and other conditions may cause nausea and vomiting.

Therapeutic Measures

Nausea and vomiting may be self-limited and require no intervention. If it is prolonged, however, dehydration and electrolyte imbalances can occur. The loss of hydrochloric acid from the stomach can result in metabolic alkalosis. Emesis that looks like coffee grounds (dark brown) occurs from bleeding in the stomach and requires further assessment.

Nursing Process for the Patient With Nausea and Vomiting

Data Collection

The characteristics of the episodes of the nausea and vomiting are noted. Medical conditions, medications, and treatments are documented to aid in diagnosing the cause. Signs of early fluid deficit, such as weakness, headache, muscle cramps, restlessness, inability to concentrate, and postural hypotension, are reported for treatment. Later signs include confusion, oliguria, cold clammy skin, and chest or abdominal pain.

Nursing Diagnoses, Planning, and Implementation

**Clinical Question**

Does ginger help alleviate chemotherapy-induced nausea and vomiting (CINV)?

**Evidence**

Ginger has been used as a nonpharmacologic intervention to prevent and treat CINV as well as postoperative and pregnancy induced nausea and vomiting. Studies have been conducted to evaluate the effectiveness of ginger at relieving CINV in many patients. A systematic review was conducted of five randomized, controlled trials involving 872 patients with cancer. Ginger was compared with placebo or metoclopramide. The incidence and severity of acute and delayed CINV were subject to meta-analysis. The incidence of acute nausea \( (p = .67) \), incidence of acute vomiting \( (p = .37) \), and severity of acute nausea \( (p = .12) \) did not differ significantly between the ginger and control groups (Lee & Ho, 2013). In another meta-analysis, Marx et al (2013) found mixed results in that some patients experienced relief from CINV, but others had mixed results and some patients had no relief.

**Implications for Nursing Practice**

Research has not established that ginger is an effective means to control CINV. More research and controlled studies are needed before clinical use can be recommended.

**REFERENCE**

**EVIDENCE-BASED PRACTICE**

**Clinical Question**

Does ginger help alleviate chemotherapy-induced nausea and vomiting (CINV)?

**Evidence**

Ginger has been used as a nonpharmacologic intervention to prevent and treat CINV as well as postoperative and pregnancy induced nausea and vomiting. Studies have been conducted to evaluate the effectiveness of ginger at relieving CINV in many patients. A systematic review was conducted of five randomized, controlled trials involving 872 patients with cancer. Ginger was compared with placebo or metoclopramide. The incidence and severity of acute and delayed CINV were subject to meta-analysis. In another meta-analysis, Marx et al (2013) found mixed results in that some patients experienced relief from CINV, but others had mixed results and some patients had no relief.

**Implications for Nursing Practice**

Research has not established that ginger is an effective means to control CINV. More research and controlled studies are needed before clinical use can be recommended.

**REFERENCE**

Chapter 33  Nursing Care of Patients With Upper Gastrointestinal Disorders  719

• Teach patient to avoid triggering fluids or foods to prevent nausea and vomiting.

Risk for Aspiration related to decreased gag reflex or unconsciousness

**EXPECTED OUTCOME** Patient’s airway and lung sounds will remain clear at all times.

• Identify patients who are nauseated and at risk of aspiration to plan preventive care.
• Turn patient onto side if nauseated and vomiting to protect airway and prevent aspiration.

Deficient Fluid Volume

**EXPECTED OUTCOME** Patient’s vital signs will remain within normal limits. Monitor for early signs of hypovolemia in patients with vomiting to allow treatment and prevent complications.

• Obtain daily weight on same scale, at same time of day, with same type of clothing to detect fluid losses. (A 1-pound weight loss reflects a fluid loss of 500 mL.)
• Monitor intake and output and vital signs including orthostatic blood pressure per shift or daily or more frequently as patient’s condition indicates to report changes for prompt treatment.
• Provide fluids as ordered to hydrate patient. IV fluids allow the GI tract to rest. Slightly chilled sports replacement drinks or ginger ale may be given in small amounts at frequent intervals.
• Monitor older adults for excess fluid volume during treatment of deficient fluid volume to prevent and detect fluid overload, which may occur quickly in the older adult.

**Evaluation**
The patient’s goals are met if nausea is not present, lung sounds remain clear, and vital signs remain within normal limits.

**EATING DISORDERS**

Anorexia

Anorexia, which is a lack of appetite, is a common symptom of many diseases and can be caused by noxious food odors, certain drugs (as an intended or side effect), emotional stress, fear, psychological problems, and infections. Prolonged anorexia with an inadequate nutritional intake can lead to serious electrolyte imbalances, which in turn can lead to cardiac dysrhythmias. Although eating is the preferred method of weight gain, other measures such as tube feedings and IV infusion can be used. Ask patients what causes them to lose their appetite and what improves it to plan their care. Nursing actions for the patient with anorexia include documenting accurate intake and output; monitoring vital signs, electrolytes, and electrocardiograms (ECGs); and monitoring the rate of the IV infusion and tube feeding.

Anorexia Nervosa

Anorexia nervosa is an eating disorder recognized by the American Psychiatric Association. This disease most commonly occurs in females between ages 12 and 18 who are from the middle and upper classes of Western culture. Males account for less than 10% of those with anorexia nervosa. Young women with low self-esteem seem to be at highest risk. Anorexia nervosa is thought to be psychological in origin. Patients may have a phobia about weight gain, be afraid of a loss of control, and be mistrusting.

Signs and Symptoms

Early signs and symptoms of anorexia nervosa include severe weight loss, low self-esteem, compulsive dieting, and an altered body image (patients imagine themselves as fat, although they are within or below normal weight range). As the disease progresses, additional symptoms appear, including electrolyte imbalance, cardiac dysrhythmias, constipation, dry skin, lanugo (downy hair covering body), bradycardia, hypothermia, hypotension, muscle wasting, and facial puffiness. Often patients with anorexia nervosa deny the existence of any problem. They may develop bizarre food rituals and sometimes weigh themselves several times a day.

Complications

Chronic poor nutritional health takes its toll on the body. Complications from starvation occur as the body tries to conserve energy. Pulse and blood pressure fall. Heart and kidney failure are a risk. Osteoporosis and muscle loss occur. Vitamin and electrolyte imbalances result. Diabetes may develop with a high morbidity.

**Therapeutic Measures**

Treating this disorder is complex and requires a multidisciplinary approach. Patients often do not see the need for medical intervention. They do not usually seek help on their own and are often resistant to treatment. When treatment is sought, often through a concerned person’s urgings, a medical and psychological workup is necessary. Nutritional status is also evaluated to determine the urgency of intervention. Establishing a trusting relationship, which can be difficult, is a key element in initiating treatment. Early treatment results in a better prognosis.

What do you think would be the most important initial intervention for anorexia nervosa? The answer is the restoration of nutritional health. Up to 18% of anorexia patients eventually die as a result of starvation and complications. For those who are underweight with severe weight loss, life-threatening electrolyte imbalances and dysrhythmias or other symptoms, nutrition is supplied by IV infusions containing electrolytes. Oral food supplements may also need to be given. Restoring normal weight is a long, slow process. Gains may be small with setbacks along the way. Praise and rewards for small achievements in weight gains (not food intake) are positive reinforcements that aid recovery. Programs that treat eating disorders are often set up on a reward system, with privileges being increased as progress occurs.

The patient’s damaged self-image and self-esteem are underlying causes of the disorder that must be addressed in conjunction with the nutritional aspect. Psychotherapy and
behavior modification that include participation of the patient’s significant others are used in treatment of anorexia nervosa. The altered body image is the main focus of therapy. Educating the patient on normal body weight can be helpful. Individual or group therapy is used. Family counseling may be used because childhood events often create the negative self-image. During treatment, a support system is vital to success. Visit www.nationaleatingdisorders.org for resources for patients and families.

Bulimia Nervosa

Bulimia nervosa is compulsive eating with self-induced vomiting, which is commonly known as binge-purge. A high percentage of patients with bulimia are young women. The patient with bulimia typically eats massive amounts of food at one sitting and then purges the food by intentionally inducing vomiting so weight is not gained. Laxatives are also sometimes used by the bulimic patient to purge the body of food to avoid weight gain. Excessive exercise may also be used to control weight.

Signs and Symptoms

Patients with bulimia nervosa exhibit many of the same signs and symptoms as patients with anorexia nervosa, with a few exceptions. Bulimic patients often have enamel erosion of the front teeth and staining caused by the acid content of the emesis. They also spend a great deal of time locked in the bathroom vomiting, especially after meals. Electrolyte imbalances occur from dehydration. The loss of potassium and sodium may result in dysrhythmias, heart failure, and death. As the electrolyte imbalance worsens, metabolic alkalosis develops as a result of the loss of gastric acid in the stomach contents. Signs and symptoms of metabolic alkalosis include hypokalemia and hypocalcemia. Laxative use results in irregular bowel movements.

Therapeutic Measures

The treatment for bulimia nervosa is essentially the same as for the patient with anorexia nervosa.

Nursing Process for the Patient With an Eating Disorder

Why do you think caring for patients with eating disorders is challenging? Gaining the patient’s genuine cooperation by using therapeutic communication and setting realistic, mutual goals is important for establishing trust and preventing relapse. To work with patients with an eating disorder a therapeutic relationship must be developed to facilitate effective interactions. Empathy, acceptance of the patient, trust, warmth, and being nonjudgmental are important.

Data Collection

Data are collected related to inadequate nutrition. Note changes in weight (15% or more below expected weight), poor skin turgor, poor muscle tone, lanugo, amenorrhea, electrolyte imbalances, and hypothermia. Data collection findings may also include a normal weight, enamel erosion of front teeth, and metabolic alkalosis for the patient with bulimia. Note abnormal diagnostic studies such as anemia, electrolyte imbalances, altered endocrine studies, and ECG changes.

Nursing Diagnoses, Planning, and Implementation

Imbalanced Nutrition: Less Than Body Requirements related to inadequate food intake, self-induced vomiting, and/or chronic/excessive laxative use

**EXPECTED OUTCOME:** The patient will establish dietary pattern and gain weight toward desired individual weight range.

- Monitor patient’s weight to determine baseline and monitor patient’s progress toward goal.
- Monitor vital signs and laboratory studies to detect changes in cardiac function related to electrolyte imbalances.
- Promote consistent approach to enhance acceptance by patient and to build trust.
- Promote pleasant eating environment and record intake to enhance patient intake.
- Provide six small meals and snacks to prevent gastric dilation.

Disturbed Body Image related to psychosocial or cognitive/perceptual changes

**EXPECTED OUTCOME:** The patient will verbalize satisfaction with body appearance.

- Assess and document patient’s verbal and nonverbal responses to own body to provide baseline understanding of patient’s perceptions of body image.
- Listen to patient and acknowledge reality of concerns regarding treatment and progress to establish therapeutic relationship.
- Monitor frequency of negative statements about self to determine if interventions are helping patient.
- Assist with referrals to social services or counseling to help patient overcome psychosocial issues.
- Provide care in a nonjudgmental manner to maintain the patient’s dignity.
- Use positive praise when patient verbalizes positive comments about own body.
- Encourage patient to verbalize consequences of eating disorder that have influenced self-concept to help patient realize the negative impact of the eating disorder.

Evaluation

The patient’s goals are met if the patient gains weight toward expected weight goal and if the patient verbalizes satisfaction with body appearance and increases the number of positive statements about own appearance.

**OBESITY**

Several methods can be used to diagnose a patient as overweight or obese, although there is no single, definitive measure...
Factors such as age, body frame size, and gender can influence these measurements:

- **Height-weight chart**: Weight 10% to 20% above ideal body weight is overweight; 20% or more above ideal body weight is obese.
- **Waist-to-hip ratio**: Waist-to-hip ratio is waist measurement divided by hip measurement.
- **Body mass index (BMI)**: BMI, calculated using height-to-weight ratios, is one of the best methods for defining obesity (see Fig. 33.1).

People who are overweight or obese are at increased risk for developing other diseases. Diseases associated with being overweight or obesity are called comorbidities and can include atherosclerosis, gallbladder disease, heart disease, hypertension, osteoarthritis, sleep apnea, type 2 diabetes mellitus, decreased mobility, lack of self-esteem, and depression. When combined with a high-fat diet, there is also an increased risk of breast, colon, rectum, and prostate cancer. For more information, visit the Centers for Disease Control and Prevention (CDC) at www.cdc.gov/nccdphp/dnpa/obesity/defining.htm.

Obesity is caused by a caloric intake that exceeds energy expenditure. Only a small percentage of obesity is associated with a metabolic or endocrine abnormality. Obesity that interferes with activities of daily living, such as breathing or walking, is known as morbid obesity. Morbid obesity refers to people whose BMI is above 40, which is about 100 lb overweight for men and about 80 lb overweight for women. Surgery can be an option for people whose BMI is above 40 or for people whose BMI is between 35 and 40 and who have life-threatening obesity-related diseases such as severe sleep apnea or heart disease. For more information, visit the CDC (www.cdc.gov/obesity/adult/defining.html) or American Obesity Association (www.obesity.org).

### Therapeutic Measures

Initial treatment for obesity is weight loss through education regarding a healthy and balanced diet, exercise, and calorie restriction. For weight loss to occur, the patient must cooperate and have sustained motivation. Support groups such as Take Off Pounds Sensibly (TOPS.org) and Weight Watchers can help patients be successful. Behavior modification methods that provide rewards for successful weight loss are often included in a weight loss plan. Short-term use of medications that suppress appetite or block fat absorption may also be used.

### Bariatric Surgery

Patients who do not respond to medical methods of weight loss, who weigh 100 pounds over ideal body weight, have a BMI over 40, or have a BMI over 35 with severe health effects as a result might be candidates for surgical weight loss (“Patient Perspective”). Additional screening for psychiatric and social stability is required.

Weight loss surgery is called bariatric surgery. The word **bariatric** comes from the Greek word *baros*, which means “weight.” Surgical techniques produce weight loss by limiting how much the stomach can hold and/or decreased calorie and nutrient absorption (“Nutrition Notes”). One benefit of the gastric surgeries is that type 2 diabetes can improve by varying degrees with each type of surgery. For a list of surgical weight loss centers and surgical procedures, visit the American Society for Bariatric Surgeons at www.asbs.org.

### Adjustable Gastric Banding

Laparoscopic adjustable gastric banding is done with an inflatable silicone band placed around the upper portion of the

**Patient Perspective**

**Curtis**

I am 47, with eight children. For many years, I experienced weight control problems. By the time I was in high school, I weighed 250 pounds, and the weight just kept building from there. I had tried many weight control programs, including some medications that now have been removed from the market.

When I was about 38, I began to look into weight loss surgeries such as the Roux-en-Y. Many of the older techniques were dangerous and risky. Even the newer procedures are major procedures with many risks.

I had spoken to many people who had bariatric surgery. Many pointed out the psychological aspect, talking about how differently people treated you after weight loss, and how some couples ended up divorcing. This was a very scary aspect to me.

However, after much research and after reaching a weight of about 380 pounds, I arranged to have the surgery. I had my surgery at a facility that did only bariatric surgery. I felt very comfortable through the whole process. This included all the presurgical testing, including psychological evaluation and counseling.

One of the nice features was that the facility itself was patient-friendly, with large chairs and other amenities for larger people. When I had the surgery I had a rough first 24 hours, spent in the critical care unit. The nursing staff was very professional and understanding. The care was personal and responsive to my needs. The staff was courteous and made me comfortable.

I think that understanding the medical field you are working in is important to this feeling of patient comfort. Several of my nurses had gone through the procedure themselves. This really helped them to know what I was experiencing. Nurses should be well informed about the procedures.

It has been 6+ years now, and I have continued to keep my weight down around 230 to 250 pounds, which is a loss of approximately 120 pounds. My health has improved a good deal. I would do it again, even though at about day 21, I would have said “never again.”

As nursing professionals, it is very important to treat all patients as human beings and with much respect regardless of their socioeconomic status or medical needs. If patients are treated with respect and caring, it is a step for them in the right direction. I believe it is not only kind but helps in the healing and recovery processes as well. I was treated with a great deal of kindness and respect during my procedure and I greatly appreciated this. Thanks to all the professional nurses out there who do a great job.

---

**Nutrition Notes**

**Supplying Nutrition in Upper Gastrointestinal Conditions**

**Bariatric Surgery**

Candidates for bariatric surgery should be carefully selected and instructed that the procedure is a tool to assist with weight control, along with behavioral changes, diet and exercise. If the patient overeats, the small pouch can be stretched and the weight regained.

Intake is rigidly controlled in type and amount immediately after the surgery and during approximately 12 weeks of rehabilitation. Long-term dietary strategies include the following:

- Eating three to six small balanced meals daily
- Choosing high protein, low fat, low sugar foods
- Chewing thoroughly and eating slowly
- Drinking sufficient fluids, mostly between meals
- Taking vitamin and mineral supplements as prescribed.

Nutritional ramifications following bariatric surgery are legion. The most common clinically relevant micronutrient deficiencies after gastric bypass include those of thiamin, vitamin B₁₂, vitamin D, iron, and copper. Also, intakes of less than recommended amounts of calcium, magnesium, and phosphorus have been reported. As many as 30% of postoperative patients reported intolerance to certain foods. One case of severe scurvy was diagnosed 3 months postoperatively in a patient who rejected dietary advice.

Potential complications of these surgeries include nausea, vomiting, bloating, heartburn, staple disruption, obstruction, dumping syndrome (rapid entry of food into the jejunum without proper mixing of the food with digestive juices), gout, gallstones, kidney stones, and osteoporosis.

**Gastroesophageal Reflux and Hiatal Hernia**

Thorough chewing and correct timing of intake is helpful in controlling symptoms:

- Eat six small meals
- Limit liquids with meals if they cause distention or satiety
- No food within 3 hours of bedtime
- Avoiding certain substances can alleviate symptoms.
  - Those that relax the sphincter:
    - Fat and chocolate
    - Peppermint and spearmint
    - Caffeine and alcohol
  - Those that stimulate gastric secretions:
    - Coffee and tea, regular or decaffeinated
    - Pepper
  - Those that may be irritating:
    - Citrus juices
    - Tomatoes, tomato juice and sauces
Postprandial Hypotension
This refers to a drop in systolic blood pressure of 20 mm Hg or more within 2 hours of beginning a meal. Symptoms are dizziness, weakness, lightheadedness, fials, disturbed speech, and vision changes. Complications are angina pectoris and stroke.

Normally, the body compensates for the increased blood flow to the digestive tract after meals, but in older adults, the mechanisms maintaining adequate circulation to the rest of the body become less effective. Most at risk are people with hypertension or impaired control of the autonomic nervous system. Greater effects are seen when the stomach empties rapidly.

To prevent postprandial hypotension, a person should:
• Drink 12 to 18 ounces of water 15 minutes before meals to enhance fluid balance.
• Limit carbohydrate intake.
• Eat frequent small meals.
• Lie in a semirecumbent position for 90 minutes after eating.
• Schedule antihypertensive medications between rather than just before meals.

Special dietary additives or medications to delay gastric emptying are sometimes prescribed.

Dumping Syndrome
The recommended meal pattern for patients with dumping syndrome includes six small meals per day that are high in protein and fat but low in simple sugars; fluids between rather than with meals; and reclining for 30 to 60 minutes after meals. Supplementation with the vitamins B12 and D, folic acid, and the minerals calcium and iron may be necessary to prevent deficiencies.

Gastric Cancer
If a patient has a poor prognosis after a total gastrectomy for cancer, dietary interventions should focus on symptoms the patient wishes to control. An overly restricted diet that causes the patient discomfort or distress is inappropriate.
keep the head of the bed elevated to ensure adequate lung expansion. Patients are started on a clear liquid diet because of the small stomach pouch that has been created. Only a small amount of fluid, 30 mL, is allowed at a time. Then the diet progresses to full liquids, pureed foods, and, finally, at about 6 weeks after surgery, regular foods as tolerated. Patients will need to be taught to restrict the amount of food ingested at one time.

Bariatric patients will need long-term follow-up. Many patients experience significant weight loss by 6 to 8 months after surgery. This can lead to a large amount of flabby skin. It is recommended that they wait at least 1 full year before having reconstructive surgery to remove the excess skin.

**Nursing Process for the Patient Who Is Obese**

**Data Collection**

Data collection for the patient with obesity should include measurements of height, weight, and BMI. Information about eating patterns and exercise patterns should be obtained. The nurse should determine if any problems exist for the patient related to excess weight such as physical limitations, social interaction issues, and personal issues (e.g., changes in sexuality or financial status). The nurse should complete a complete physical assessment noting any abnormalities. Assessment should include any areas in which the patient has expressed concerns or problems. Persons who are overweight have an increased risk for other diseases. The nurse should assess for signs and symptoms of disease.

**Nursing Diagnoses, Planning, and Implementation**

**Imbalanced Nutrition: More Than Body Requirements related to caloric intake greater than metabolic needs and/or decreased activity level**

**EXPECTED OUTCOME:** The patient will achieve and maintain weight loss to specified weight.

- Establish desired weight goal and monitor weight to track progress toward goal.
• Modify eating habits and patterns to lose weight and then maintain weight loss.
• Establish and maintain increased activity pattern to lose weight and then maintain weight loss.
• In collaboration with a dietician, implement eating plan for patient to safely reduce weight and maintain adequate protein intake.
• Discuss realistic weight loss goals of 1 to 2 lb/week to achieve lasting weight loss effects.
• Discuss emotions, events, and patterns of eating to help patient identify when she or he is eating to satisfy an emotional need versus a physiological hunger.
• In collaboration with physician, establish increased activity pattern to promote weight loss.
• Provide preoperative instructions if surgical interventions are planned to help patient understand the procedure.

Evaluation
The patient’s goals are met if the patient maintains progressive weight loss to specified weight goal and safely progresses through the perioperative period if a surgical intervention is completed.

NURSING CARE TIP
For the patient who is obese, it is often necessary to have on hand special bariatric equipment for patient care. Some items you may need include:

• Larger hospital bed, wheelchair, or walker
• Patient lifting devices
• Extra pillows to ease breathing
• Larger hospital gowns
• Larger blood pressure cuff

ORAL HEALTH AND DENTAL CARE

Good oral health care is important to overall health. Nutrition can be affected if oral problems interfere with eating and drinking. Respiratory illness and cardiac disease are associated with pathogens in the mouth. Regular mechanical oral hygiene is needed to remove plaque and prevent infections. Functional limitations may interfere with self-care for oral hygiene especially for older adults (“Gerontological Issues”).

Regular dental care is also important in the prevention of infections (Box 33-1). Providing oral hygiene using oral chlorhexidine gluconate (germicidal) mouthwash has been shown to be effective in preventing pneumonia in long-term care residents as well as reducing ventilator-associated pneumonia in cardiac surgery patients. Suction toothbrushes are available for those patients who are unable to control secretions (see Fig. 2.2).

Aging changes as well as disease and treatment can result in oral inflammation and infection. Those who are

Box 33-1 Common Concerns in Oral Health and Dental Care

Oral care is important throughout life and has been found to have a link to cardiac health. The importance of daily and ongoing oral care should be considered for all patients, especially older adults.

Patients who have artificial joints or some heart conditions who must undergo a dental procedure need to take prophylactic antibiotics before some dental procedures to prevent bacteria entry and bacterial endocarditis. The dentist should be informed of the patient’s history so that appropriate antibiotics can be prescribed.

Xerostomia (Dry Mouth)

As people age, it is not unusual for them to experience a condition known as xerostomia (dry mouth). Also, some medications and radiation treatment of the head and neck areas can cause it. Xerostomia can lead to rampant tooth decay in older adults, putting their dentition at risk. Before any radiation therapy of the head or neck area, a thorough oral examination and any needed restorative dental procedures should be completed.

Although water is used as a common substitute for saliva, it does not contain the necessary compounds, such as lubricants, to protect the teeth. There are many products available for dry mouth, such as Biotene gel, Act rinse, and sprays to help with the discomfort of dry mouth. Brushing with a high fluoride toothpaste that is available by prescription is also recommended.

Dentures

It is helpful to have a person’s name implanted into his or her dentures to avoid lost or mixed up dentures, especially when the person lives in an extended care facility. This service can be requested when the dentures are made, and the dentist will place a small identity tag in the acrylic of the denture with the person’s name on it.

Those with complete dentures still need to be routinely screened by a dentist or dental hygienist for proper denture fit, sore areas, oral cancer detection, and oral fungal infections.

Gingival Recession

As people age, it is not unusual for their gingivae (gums) to recede or shrink, exposing the root surfaces of the teeth. This can lead to root sensitivity, tooth decay, or both.

To protect the teeth from tooth decay as a result of dry mouth or gingival recession, a fluoride gel (Gel-Kam), rinse (Act), or a prescription toothpaste with high fluoride is strongly recommended.

Continued
immunosuppressed (i.e., with acquired immunodeficiency syndrome; AIDS) or undergoing chemotherapy or who have vitamin deficiencies are more at risk. Candidiasis is a common oral infection that is treated with nystatin oral swish and swallow. During data collection, especially in these higher risk patients, the nurse should note any oral signs of inflammation or infection requiring prompt treatment.

### ORAL INFLAMMATORY DISORDERS

#### Stomatitis

**Stomatitis** is inflammation of the oral cavity. There are many causes of stomatitis, such as an infection or a systemic disease.

#### Aphthous Stomatitis (Canker Sores)

Aphthous stomatitis appears as small, white, painful ulcers on the inner cheeks, lips, tongue, gums, palate, or pharynx and typically lasts for several days to 2 weeks. Self-induced trauma such as biting the lips and cheeks can cause these ulcers to develop, as can stress or exposure to irritating foods. Application of topical tetracycline several times a day usually shortens the healing time. A topical anesthetic such as benzocaine or lidocaine provides pain relief and makes it possible to eat with minimal pain.

#### Herpes Simplex Virus Type 1 Infection

Herpes simplex virus type 1 (HSV-1) infection may appear as painful cold sores or fever blisters on the face, lips, perioral area, cheeks, nose, or conjunctivae. These lesions recur over time but last only for a few days each time. The onset can be provoked by fever or stress, among other things. Acyclovir ointment can be used to ease the pain, but it does not cure the lesions. Oral acyclovir may reduce recurrences. These lesions are infectious, and standard precautions should be used when ointment is applied or oral care is given.

### ORAL CANCER

#### Pathophysiology and Etiology

Oral cancer can occur anywhere in the mouth or throat. If detected early enough, it is curable. Oral cancer is found most commonly in patients who use alcohol or any form of tobacco. The highest incidence of oral cancer is found in the pharynx (throat), with the lowest incidence being on the lips.

#### Signs and Symptoms

Any oral sore that does not heal in 2 weeks should be assessed by the patient’s physician. Cancerous ulcers are often painless but may become tender as the cancer progresses. In the later stages, the patient may report difficulty chewing, swallowing, or speaking or may have swollen cervical lymph glands.

#### Diagnostic Tests

Biopsy specimens are taken to determine the presence of cancer.

#### Therapeutic Measures

Oral cancer treatment varies depending on the individualized diagnosis. Radiation, chemotherapy, and surgery are used alone or in combination to treat oral cancer. Radical or modified neck dissection is often performed because this type of
cancer frequently has metastasized to cervical lymph nodes by the time it is diagnosed (Fig. 33.3). The tumor is removed along with lymph nodes, muscles, blood vessels, glands, and part of the thyroid, depending on the extent of the cancer. Drains are inserted into the incision to prevent fluid accumulation. A tracheostomy is usually performed to protect the airway and prevent obstruction.

**Nursing Care**

Preoperative and postoperative nursing care is discussed in Chapter 12. Preoperatively, the use of alcohol or tobacco is addressed and referrals to cessation programs and support groups offered. Preoperative teaching includes how the patient will communicate if a tracheostomy is placed. Postoperatively, major concerns are airway patency, communication, and nutritional needs. Nursing care for the patient with a tracheostomy is discussed in Chapter 29. The airway must be monitored and secretions controlled to prevent aspiration. Determining that the methods the patient is using for communication are satisfactory is evaluated. Tube feedings (see Chapter 32) are usually given to meet the patient’s nutritional needs because swallowing is difficult.

**ESOPHAGEAL CANCER**

**Pathophysiology and Etiology**

As with oral cancer, esophageal cancer is associated with the use of tobacco or alcohol. Barrett’s esophagus, a precancerous condition, is a risk factor. Esophageal cancer is usually detected in advanced stages because of its location near many lymph nodes that allow it to metastasize. As the cancer progresses, obstruction of the esophagus can occur with possible perforation or fistula development that may cause aspiration.

**Signs and Symptoms**

Signs and symptoms may include progressive dysphasia (difficulty swallowing), a feeling of fullness, pain in the chest after eating, foul breath, or regurgitation of foods if there is an obstruction.

**Diagnostic Tests**

Diagnosis of esophageal cancer can be made by barium swallow studies, biopsy, or endoscopy procedures such as esophagogastroduodenoscopy (EGD) or mediastinoscopy (endoscopic examination of mediastinum). Mediastinoscopy is used to determine whether the cancer has spread to the lymph nodes and surrounding structures.

**Therapeutic Measures**

Treatment for esophageal cancer includes surgery (most common), radiation, chemotherapy, laser therapy, and electrocoagulation. These therapies may be used alone or in combination. Surgical procedures include esophageal resection (esophagectomy), resection of the esophagus and anastomosis to the remaining part of the stomach (esophagogastrostomy), Dacron esophageal replacement, or use of a section of colon to replace the esophagus (esophagoenterostomy). If the tumor is inoperable, esophageal dilation or stent placement can be done to relieve dysphagia and allow food to pass through the esophagus.

**Nursing Process for the Patient With Esophageal Cancer**

The patient with esophageal cancer may undergo various forms of treatment: chemotherapy, radiation, or surgery. Nursing care is provided based on the effects of the therapies (see Chapters 11 and 12).

**Data Collection**

Patient data are collected for risk factors of esophageal cancer, pain, dysphagia, and nutritional status.

**Nursing Diagnoses, Planning, and Implementation**

**Pain related to tumor and pressure exerted on surrounding tissues**

**EXPECTED OUTCOME**: Patient will state a reduction of pain to acceptable level or total relief of pain within 30 minutes of report of pain.

- Assess pain level using pain rating scale to identify pain level.
- Provide pain medications as ordered to provide pain relief.

**Risk for Deficient Fluid Volume related to decreased intake**

**EXPECTED OUTCOME**: Patient’s vital signs will remain within normal limits and intake and output will be balanced for 24 hours at all times.

- Assess fluid intake and swallowing ability with fluids to plan care.
• Obtain daily weights to detect changes in fluid volume.
• Provide fluids as able to swallow to ensure adequate intake.
• Monitor IV infusion as ordered to prevent hypovolemia.
• Monitor vital signs and report abnormal findings for prompt treatment.

Imbalanced Nutrition: Less Than Body Requirements related to dysphagia

EXPECTED OUTCOME: Patient will maintain weight within normal limits for body frame, and laboratory values such as albumin, electrolytes, and lymphocytes will be within normal limits.

• Obtain patient height and weight, and weigh weekly to monitor changes during care.
• Identify patient’s ability to swallow and eat food to determine plan of care.
• Provide oral care frequently to refresh mouth and encourage desire to eat.
• Provide nutrition as ordered in form patient is able to tolerate (liquid supplements, tube feedings, parenteral nutrition, etc.) to maintain adequate nutrition.

Evaluation
The goals are met if the patient reports pain is relieved and fluid volume and nutritional needs are met.

HIATAL HERNIA

Pathophysiology
The esophagus passes through an opening in the diaphragm called the hiatus. A hiatal hernia is a condition in which the stomach slides up through the hiatus of the diaphragm into the thorax (Fig. 33.4). A sliding hiatal hernia is the most common type in which the junction of the stomach and esophagus slides up into the thoracic cavity when a patient is supine and then usually goes back into the abdominal cavity when the patient stands upright. A paraesophageal hernia is rarer but serious as part of the stomach squeezes through the hiatus and is at risk for strangulation (blood supply is cut off). Hiatal hernia occurs most commonly in smokers, those who are older than age 50, obese, or pregnant. People with hiatal hernia often have gastroesophageal reflux disease (GERD) as well (discussed later).

Signs and Symptoms
A small hernia may not produce any discomfort or require treatment. However, a large hernia can cause pain, heartburn, a feeling of fullness, or reflux, which can injure the esophagus with possible ulceration and bleeding.

Diagnostic Tests
Hiatal hernias are diagnosed by x-ray studies and fluoroscopy.

Therapeutic Measures
Lifestyle changes for symptomatic hiatal hernia include losing weight, taking antacids, eating small meals that pass easily through the esophagus, not reclining for 3 to 4 hours after eating, elevating the head of the bed 6 to 12 inches to prevent reflux, and avoiding bedtime snacks, spicy foods, alcohol, caffeine, and smoking (see “Nutrition Notes”).

Surgical Management
Surgery is done for symptomatic hiatal hernia when GERD, strangulation, or obstruction is present. Fundoplication, in which the stomach fundus is wrapped around the lower part of the esophagus, is the most common surgical procedure performed (Fig. 33.5).

Nursing Care
The patient is taught lifestyle interventions to reduce the symptoms of hiatal hernia. If the patient undergoes surgery, general postoperative nursing care is provided. In addition, following fundoplication, patients are assessed for dysphagia during their first postoperative meal. If dysphagia occurs, the physician should be notified because the repair may be too tight, causing obstruction of the passage of food.

GASTROESOPHAGEAL REFLUX DISEASE

Pathophysiology
GERD is a condition in which gastric secretions reflux into the esophagus. The esophagus can be damaged by acidic gastric secretions and exposure to digestive enzymes. GERD is caused primarily by conditions that affect the ability of the lower esophageal sphincter to close tightly, such as hiatal hernia.
Signs and Symptoms

Signs and symptoms of GERD include heartburn, regurgitation, dysphagia, and bleeding (Table 33.1). Aspiration is a concern. Scar tissue can develop from the inflammation.

Diagnostic Tests

Diagnostic tests include a barium swallow, esophagoscopy (an endoscopic procedure), or pH monitoring of the normally alkaline esophagus.

Complications

Complications of GERD can result in esophagitis (inflammation of the esophagus) due to acid reflux. Over time this can lead to changes in the epithelium of the esophagus and lead to Barrett’s esophagus. This is a precancerous lesion that puts the patient at risk of developing esophageal cancer. Barrett’s tissue can be removed during a 30-minute outpatient endoscopic procedure using radiofrequency ablation (the BARRx system). Normal tissue returns, and the risk of cancer is reduced. Respiratory complications such as bronchospasm, laryngospasm, and aspiration pneumonia can also occur owing to aspiration of gastric contents. There is the potential for asthma, chronic bronchitis, or pneumonia due to the aspiration of gastric contents.

Therapeutic Measures

Lifestyle changes are recommended along with medications. Obese patients are encouraged to lose weight. A low-fat, high-protein diet is recommended because fat causes decreased functioning of the lower esophageal sphincter. See “Nutritional Notes” for additional things to avoid. Patient teaching includes eating small meals often during the day drinking fluids between meals instead of with meals, avoiding late evening meals, snacking, and fluids 2 to 3 hours before bedtime. Medications may include nonprescription antacids for mild symptoms. Histamine (H2) receptor antagonists (acid reducers) that are available in nonprescription and prescription strengths are used for mild to moderate symptoms. Proton pump inhibitors (PPIs) reduce acid in the stomach and are used for frequent, severe symptoms and Barrett’s esophagus. (Table 33.4 later in this chapter provides information on PPIs.) There are suspected risks associated with PPI use that includes a possible increased risk of osteoporosis and Clostridium difficile infection. If diarrhea occurs that does not stop, patients should contact a health care provider (HCP; Janarthanan, Ditah, Adler, & Ehrinpreis, 2012).

Surgery can be done if necessary to alleviate symptoms. A fundoplication or endoscopic procedures can be done. As you read, what do you think the benefit of the following procedure is over fundoplication surgery? A minimally invasive procedure, transoral incisionless fundoplication (TIF) is performed through the mouth without incisions. It employs the EsophyX device to create an esophagogastrectomy fundoplication that is up to 270° and 2 to 3 cm in length. EsophyX, uses an endoscope to tighten the lower esophageal sphincter, which aids in improving or eliminating gastroesophageal reflux with good success (www.endogastricsolutions.com/TIF.aspx). If you thought that the benefit of TIF is that it’s minimally invasive and, therefore, has a speedier recovery, you would be correct. Other
endoscopic procedures that use radiofrequency waves, such as the Stretta, can be done. The radiofrequency waves are injected into the lower esophageal sphincter muscle to form collagen contraction, which leads to a barrier against reflux.

**Nursing Process for the Patient With GERD**

**Data Collection**

Assessment of the patient with GERD includes evaluation of reports of heartburn. The onset, duration, characteristics, and precipitating or relieving factors are noted.

**Nursing Diagnoses, Planning, and Implementation**

**Acute Pain related to inflammation of esophageal tissues**

**EXPECTED OUTCOME:** The patient will state a reduction of pain to an acceptable level or total relief of pain within 30 minutes of report of pain.

- Identify factors that increase pain to develop teaching plan.
- Monitor pain level using pain rating scale to identify pain level.
- Instruct patient regarding factors that aggravate pain to enhance management of condition.
- Instruct patient to sleep with head of bed elevated 4 to 6 inches, eat small meals, and avoid lying down for 2 hours after eating to prevent reflux of gastric contents into esophagus.
- Instruct patient to avoid smoking and alcohol because they decrease functioning of the lower esophageal sphincter.
- Instruct patient to avoid foods that cause discomfort to avoid pain.
- Review medication schedule and teach patient to take medications even if symptoms are relieved because the underlying pathology still exists.
- Provide pain medications on routine schedule, especially postoperatively, to provide optimum pain relief and control.

**Evaluation**

The goals are met if the patient is able to manage medications, pain is controlled, and symptoms are relieved.

---

**MALLORY-WEISS TEAR**

**Pathophysiology**

A Mallory-Weiss tear (MWT) is a longitudinal tear in the mucous membrane of the esophagus at the stomach junction (gastric cardia). These tears occur from a sudden powerful or prolonged force due to coughing, vomiting, seizures, prolapse of the stomach into the esophagus, or cardiopulmonary resuscitation (CPR). Hiatal hernia is present in most patients with MWTs.

**Signs and Symptoms**

Bleeding may result from the tear. Up to 15% of GI bleeding is caused by MWTs. Symptoms include bright red, bloody emesis or bloody or tarry stools.

---

**ESOPHAGEAL VARICES**

Esophageal varices are dilated blood vessels in the esophagus (see Chapter 35). Their rupture can precipitate a life-threatening event. Varices develop from portal hypertension. This occurs when pressure rises in the portal vein from blocked blood flow in the liver. This is often due to cirrhosis of the liver.

**GASTRITIS**

Gastritis is inflammation of the stomach mucosa and can be acute or chronic. Causes are listed in Box 33-2.

**Acute Gastritis**

**Pathophysiology**

Gastritis results when the protective mucosal barrier is broken down and allows autodigestion from hydrochloric acid and pepsin to occur. This results in edema of the tissue and possible hemorrhage. With severe gastritis, the gastric mucosa can become gangrenous and perforate, which can lead to peritonitis (infection of the peritoneum). Scarring may also occur, resulting in pyloric obstruction.

---

**Diagnostic Tests**

The tear can be diagnosed with an esophagogastroduodenoscopy (EGD). Hemoglobin and hematocrit are checked to determine amount of bleeding.

**Therapeutic Measures**

The tears usually self-heal without intervention in several days, and bleeding stops within a few hours. It is rare to have it happen again. Medications such as a PPI and an antiemetic may be given. Alcohol use should be avoided. Up to 75% of those with MWT use alcohol excessively. Rarely, excessive bleeding may occur, resulting in shock and/or the need for a blood transfusion. Bleeding is treated with injection of epinephrine to constrict the blood vessel, and during endoscopy, endoclips can be placed to stop the bleeding. The prognosis for MWTs is good. The condition is seen in men more often than in women.

**Nursing Care**

Monitoring the patient for signs of bleeding and reporting them to prevent complications from hemorrhage are the focus of nursing care. If excessive bleeding occurs, shock symptoms may occur and require prompt intervention. Teaching about medications and the avoidance of alcohol use is also done. See the section on gastric bleeding later in the chapter for more information.
Signs and Symptoms
The major symptom of gastritis is abdominal pain, which is often accompanied by nausea and anorexia. The patient may also experience abdominal tenderness, a feeling of fullness, reflux, belching, and hematemesis. If the cause of the gastritis is contaminated food, symptoms including diarrhea usually start within 5 to 6 hours.

Therapeutic Measures
Treatment of gastritis is removal of the irritating substance and provision of a bland diet of liquids and soft foods along with antacids. Medication therapy may include antiemetics to control vomiting and antacids and/or histamine receptor antagonists to control pain. With a bland diet, the patient usually recovers in a short period of time.

Chronic Gastritis
Chronic gastritis occurs over time and is classified as type A or type B.

Type A
Type A chronic gastritis is often referred to as autoimmune gastritis and occurs in the fundus (body of stomach). Chronic gastritis type A is diagnosed by endoscopy, upper GI x-ray examination, and gastric aspirate analysis (see Chapter 32). Type A gastritis is often asymptomatic. Patients with type A gastritis usually do not secrete enough intrinsic factor from their stomach cells and as a result have difficulty absorbing vitamin B₁₂, which leads to pernicious anemia (discussed later).

Type B
Type B chronic gastritis affects the antrum and pylorus (lower end of the stomach near the duodenum) and is associated with Helicobacter pylori bacterial infection. Type B is the most common type of chronic gastritis. Signs and symptoms include poor appetite, heartburn after eating, belching, a sour taste in the mouth, and nausea and vomiting. Type B gastritis can also be diagnosed by endoscopy, upper GI x-ray examination, and gastric aspirate analysis. H. pylori infection is treated with antibiotics.

Stress-Induced Gastritis
A small number of patients who are critically ill may develop GI mucosal damage from ischemia. The stress response to the illness causes reduced blood flow to the stomach and small intestine, resulting in ischemia and damage to the mucosa. The damaged mucous barrier then allows acid secretions to create ulcerations. Preventive treatment has dramatically reduced stress ulceration, which can have a high mortality rate because of the multiple bleeding ulcer sites. This treatment includes trauma care that quickly restores oxygen to the stomach, as well as early feeding within 24 hours of the trauma and prophylactic sucralfate (forms a gel that binds to the base of an ulcer), antacids, or histamine blockers.

PEPTIC ULCER DISEASE

Pathophysiology
Peptic ulcer disease (PUD) is a condition in which the lining of the stomach, pylorus, duodenum, or the esophagus is eroded, usually from infection with H. pylori. The erosion may extend into the muscular layers or the peritoneum. Peptic ulcers occur in the portions of the GI tract that are exposed to hydrochloric acid and pepsin. The erosion is due to an increase in the concentration or activity of hydrochloric acid and pepsin. The damaged mucosa is unable to secrete enough mucus to act as a barrier against the hydrochloric acid. Some individuals have more rapid gastric emptying, which, combined with hypersecretion of acid, creates a large amount of acid moving into the duodenum. As a result, peptic ulcers occur more often in the duodenum. Ulcers are named by their location: esophageal, gastric, or duodenal. Duodenal ulcers are more common than gastric ulcers.

Etiology
Until 1982, the cause of peptic ulcers was poorly understood and thought to be related to stress, diet, and alcohol or caffeine ingestion. However, research results have found that PUD is primarily caused by infection with the Gram-negative bacterium H. pylori. This bacterium is responsible for 80% of gastric ulcers and more than 90% of duodenal ulcers. Two-thirds of all people are infected with H. pylori, and it is most common in those who are older adult Hispanics, African Americans, or in lower socioeconomic groups in the United States. The discovery of H. pylori has led to changes in treating and curing peptic ulcers. It is not known how H. pylori is
transmitted, although the oral-oral or fecal-oral route is likely. Contaminated water may also play a role. Vaccines to prevent peptic ulcers are being developed.

**LEARNING TIP**

Most peptic ulcers are caused by an infection (H. pylori) that can be cured with antibiotics. Risk factors that contribute to peptic ulcer disease include smoking, chewing tobacco, stress, caffeine use, and medications such as steroids, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs). Peptic ulcer development is influenced by smoking because it increases the harmful effects of H. pylori, alters protective mechanisms, and decreases gastric blood flow. For more information on H. pylori, visit [www.cdc.gov](http://www.cdc.gov).

### Signs and Symptoms

Symptoms vary with the location of the ulcer (Table 33.2). Symptoms, including pain, may not be experienced with gastric or duodenal ulcers until complications such as hemorrhage, obstruction, or perforation develop. If pain does occur, patients with gastric ulcers commonly experience a burning and gnawing pain in the high left epigastric region, and may increase with food ingestion or 1 to 2 hours after a meal. Duodenal ulcers produce cramping or burning pain in the midepigastric or upper abdominal area, which occurs 2 to 4 hours after meals or in the middle of the night. This intermittent pain may be relieved by the ingestion of food or antacids. Anorexia and nausea and vomiting may also occur with either ulcer location. Bleeding may occur with massive hemorrhaging or slow oozing. Patients often have low hematocrit and hemoglobin levels, and gastric or fecal occult blood may be found, depending on where the ulcers are located.

| Bleeding (stomach secretions or stool positive for occult blood) | Urea breath test |                         |
Complications

Major complications can result from PUD. These include bleeding, perforation, and obstruction. Bleeding can occur in varying degrees from occult blood in stool and emesis to massive bright red bleeding. Hemorrhage tends to occur more often with gastric ulcers in older adults. The patient may experience signs and symptoms of shock. Treatment includes stopping the bleeding, replacing fluid and electrolytes, and possibly administering vasopressin to stop the bleeding.

Diagnostic Tests

*H. pylori* can be diagnosed with several tests. The urea breath test is performed by having the patient drink carbon-labeled urea. The urea is metabolized rapidly if *H. pylori* is present, allowing the carbon to be absorbed and measured in exhaled carbon dioxide. An immunoglobulin G antibody detection test for *H. pylori* identifies whether the patient is infected with *H. pylori*. These are both noninvasive detection tests. Biopsy specimens for the *Campylobacter*-like organism (CLO) biopsy urease test and a histological examination can be obtained during EGD. Biopsy is the most conclusive test for *H. pylori*. Cultures of the biopsy specimen may also be done to determine antimicrobial susceptibility.

Peptic ulcers are diagnosed on the basis of symptoms, upper GI series (barium swallow), and EGD. Endoscopy allows direct visualization of the ulcer and mucosal tissues.

Therapeutic Measures

Several treatment options are used to cure *H. pylori* without recurrence (Table 33.3). For better effectiveness, triple therapy

*Triple therapy has the best eradication rate.
with two antibiotics to decrease resistance of the bacteria and a PPI or H$_2$ antagonist is used. Treatment lasting 14 days has better eradication rates than 10-day treatments. Bismuth subsalicylate (e.g., in Pepto-Bismol$^\text{TM}$) may also be used for its antibacterial effects.

PPIs are powerful agents that stop the final step of gastric acid secretion to reduce mucosa erosion and aid in healing ulcers (Table 33.4). H$_2$ antagonists block H$_2$ receptors to decrease acid secretion, although they are not as powerful as gastric acid pump inhibitors. A bland diet may also be recommended, and foods known to cause discomfort to the patient, such as spicy foods, carbonated drinks, and caffeine, should be avoided until the ulcer heals. Alcohol should also be avoided during the healing period.

</tbody>
</table>
A perforated ulcer is a medical emergency and usually requires surgical intervention. Gastroduodenal contents escape through the perforation into the peritoneal cavity. This can result in peritonitis, septicemia, and hypovolemic shock. Perforation most often occurs with duodenal ulcers and presents with an acute onset of sharp, severe pain. Surgical treatment includes cleaning the peritoneal cavity, closing the perforation, and possibly a vagotomy and hemigastrectomy or pyloroplasty.

Obstruction may be due to scar tissue because of repeated ulcerations and healing in a patient with long-standing PUD. Obstruction frequently occurs at the pylorus, causing pain at night and vomiting. A pyloroplasty is completed to correct the problem.

### Nursing Process for the Patient With Peptic Ulcer Disease

#### Data Collection

The primary focus of nursing care for peptic ulcer disease is educating patients regarding the importance of this diagnosis because ulcers may be caused by an infection that can be cured with antibiotics. Patients may still believe that all ulcers are caused by stress, lifestyle, or diet. Assessing the patient’s knowledge aids in providing accurate information to assist the patient in managing peptic ulcer disease. Data are also collected about the patient’s disease history. Identifying factors that trigger or relieve symptoms is important.

The nurse assesses and monitors for complications of bleeding, such as occult blood in stool or emesis, perforation, including acute onset of severe pain, obstruction, changes in vital signs, and signs of shock.

#### Nursing Diagnoses, Planning, Implementation, and Evaluation

See the “Nursing Care Plan for the Patient With Peptic Ulcer Disease.” The care plan should focus on the patient’s understanding of the importance of taking all medication as directed, even if symptoms are gone.

### GASTRIC BLEEDING

Gastric bleeding may be caused by ulcer perforation, tumors, gastric surgery, or other conditions. Bleeding peptic ulcers are the most common cause of blood loss into the stomach or intestine. Blood loss can be hidden (occult) blood in the stool, observable vomited blood (hematemesis), or black tarry stools (melena). When blood mixes with hydrochloric acid and enzymes in the stomach, a dark, granular material resembling coffee grounds is produced. This material can be vomited or passed through the GI system and mixed with stools. Melena occurs from slow bleeding in an upper GI area.
### NURSING CARE PLAN for the Patient With Peptic Ulcer Disease

**Nursing Diagnosis:** *Acute Pain* related to gastric mucosal erosion

**Expected Outcome:** The patient’s pain will be relieved as evidenced by no report of pain and the absence of nonverbal pain cues within 30 minutes of report of pain.

**Evaluation of Outcome:** Is pain relieved to patient’s satisfaction?

**Intervention** Ask patient to rate pain level on scale of 0 to 10 every 3 hours and as needed. Note location, onset, intensity, characteristics of pain, and nonverbal pain cues. **Rationale** Prompt assessment can lead to timely intervention and relief of pain. **Evaluation** Does patient rate pain using scale and describe pain?

**Intervention** Ask about factors precipitating and relieving pain. **Rationale** Peptic ulcer pain may be relieved by food, antacids, or other interventions. **Evaluation** Is patient able to state precipitating and relieving pain factors?

**Intervention** Ask patient to help identify techniques for pain relief. **Rationale** Gaining the patient’s cooperation increases compliance. **Evaluation** Is patient willing to participate in planning how to relieve pain?

**Intervention** Administer antiulcer medications as ordered. **Rationale** H₂ receptor antagonists reduce amount of gastric acid produced, and antacids neutralize gastric acid to help relieve pain. **Evaluation** Do medications reduce patient’s symptoms?

**Intervention** Provide small, frequent meals four to six times a day. **Rationale** Small, frequent meals dilute and neutralize gastric acid. **Evaluation** Does patient report relief of gastric pain between meals?

**Intervention** Encourage nonacidic fluids between meals. **Rationale** Nonacidic fluids decrease irritation to gastric mucosa. **Evaluation** Does patient identify and drink nonacidic fluids?

**Nursing Diagnosis:** *Risk for Injury* related to complications of peptic ulcer activity such as hemorrhage and perforation

**Expected Outcomes:** The patient’s vital signs will be maintained within normal limits and bleeding or hemorrhage will be promptly detected.

**Evaluation of Outcomes:** Are patient’s vital signs within normal limits?

**Intervention** Monitor for signs and symptoms of hemorrhage such as hematemesis (vomiting blood) and melena (blood in the stool). **Rationale** Rapid assessment can lead to prompt intervention. **Evaluation** Does patient have any bleeding?

**Intervention** Monitor vital signs: blood pressure, pulse, respirations, and temperature. **Rationale** Severe blood loss of more than 1 L per 24 hours may cause evidence of shock, such as hypotension; weak, thready pulse; chills; palpitations; and diaphoresis. **Evaluation** Are vital signs normal?

**Intervention** Maintain IV infusion as ordered. **Rationale** Normal fluid balance prevents hypovolemia and shock due to hemorrhage. **Evaluation** Are intake and output balanced?

**Intervention** Monitor hematocrit and hemoglobin levels as ordered. **Rationale** Decreased hematocrit and hemoglobin levels indicate a decrease in circulating blood volume and reduced oxygen-carrying capacity to the tissues. **Evaluation** Are hematocrit and hemoglobin levels normal?
Signs and Symptoms
With mild bleeding, the patient may experience only slight weakness or diaphoresis (Table 33.5). Severe blood loss (more than 1 L in 24 hours) may result in hypovolemic shock, with signs and symptoms such as hypotension; a weak, thready pulse; chills; palpitations; and diaphoresis.

Therapeutic Measures
What do you think are important interventions to promote patient safety when patients experience blood loss? The goal of treatment for a massive GI bleed is to prevent or treat hypovolemic shock and prevent dehydration, electrolyte imbalance, and further bleeding. The following steps are taken:

- The patient is kept on nothing by mouth (NPO) status.
- An IV line is started to replace lost fluids and administer blood if necessary.
- A complete blood cell count is obtained to determine the amount of blood lost.
- A urinary catheter might be inserted to monitor output.
- An NG tube is inserted to assess the rate of bleeding, decompress the stomach, monitor the pH of gastric secretions, and administer saline lavage if ordered.
- Oxygen therapy may be required if the patient has lost a large amount of blood.
- To prevent aspiration with vomiting, the head of the bed is elevated.
- The physician may perform endoscopy to help control the bleeding.
- Drugs may also be instilled into the GI tract by use of an endoscope.
- For severe cases, surgery may be needed to remove the bleeding area or ligate bleeding vessels.

Nursing Process for the Patient With Gastric Bleeding
Data Collection
The nurse should assess patients at risk for bleeding for signs and symptoms of bleeding. Assess any emesis and stool for occult or obvious bleeding. Assess for signs of hypovolemic shock such as hypotension, tachycardia, tachypnea, chills, palpitations, and diaphoresis. The nurse should also assess for changes in level of consciousness, confusion, dry mucous membranes, reports of thirst, and fatigue, which could indicate a decrease in circulating blood volume.

Nursing Diagnoses, Planning, and Implementation
Deficient Fluid Volume or Risk for Deficient Fluid Volume related to vomiting and diarrhea

**EXPECTED OUTCOME** The patient’s vital signs will remain within normal limits and intake and output will be balanced over 24 hours.

- Monitor color, amount, and frequency of fluid loss to determine fluid balance changes.
- Monitor vital signs and report abnormal findings for prompt treatment.
- Monitor level of consciousness, mucous membranes, and skin turgor to assess for changes in fluid volume.
- Obtain daily weights to detect changes in fluid volume.
- Offer oral fluids to ensure adequate intake.
- Monitor IV infusion as ordered to prevent hypovolemia.
- Monitor hematocrit and hemoglobin levels as ordered to detect a decrease in circulating blood volume.

Evaluation
If interventions have been effective, vital signs are within the normal range and the patient has a balanced intake and output over 24 hours.

GASTRIC CANCER
Gastric cancer refers to malignant lesions found in the stomach. It is more common in men than in women. *H. pylori* infection plays a role in gastric cancer development. Other factors that may be associated with gastric cancer development include pernicious anemia; exposure to occupational substances such as lead dust, grain dust, glycol ethers, or leaded gasoline; and a diet high in smoked fish or meats. A poor prognosis is often associated with gastric cancer because most patients have metastasis at the time of diagnosis (see “Nutrition Notes”).

Signs and Symptoms
Gastric cancer is rarely diagnosed in its early stages because symptoms do not appear until late in the disease (Table 33.6). In the early stages, there may not be any symptoms at all, and metastasis to another organ, such as the liver, may have already occurred. The symptoms of gastric cancer are often
GASTRIC CANCER

| Signs and Symptoms          | Rarely detected during early stages
|                           | Symptoms often mistaken for PUD:
|                           | indigestion, anorexia, pain, weight loss, nausea, vomiting, anemia
|                           | Late symptoms include involvement of other organs such as the liver

| Therapeutic Measures        | Medical treatment not very effective
|                           | Surgical treatment: subtotal or total gastrectomy
| Complications               | Related to disease and surgery:
|                           | hemorrhage, acute gastric distention, nutritional problems
| Priority Nursing Diagnoses  | Acute Pain
|                           | Fear

**GASTRIC SURGERY**

Two types of surgical interventions are typically used to treat upper GI diseases: subtotal gastrectomy and total gastrectomy. There are two types of subtotal gastrectomy, which is partial removal of the stomach. It is used to treat cancer or rarely peptic ulcer disease that does not respond to therapy. For a gastroduodenostomy (Billroth I), the distal portion of the stomach is removed, and the remainder of the stomach is Anastomosed (surgically attached) to the duodenum (Fig. 33.6). A gastrojejunostomy (Billroth II) involves removal of a larger amount of the distal stomach and reanastomosis of the proximal remnant of the stomach to the proximal jejunum (see Fig. 33.6). Because it results in bypassing of the duodenum, the Billroth II procedure is used to treat duodenal ulcers. Pancreatic secretions and bile are necessary for digestion and continue to be secreted from the common bile duct even after partial gastrectomy. Total gastrectomy, the total removal of the stomach, is the treatment for extensive gastric cancer. This surgery involves total removal of the stomach, with anastomosis of the esophagus to the jejunum (Fig. 33.7). Rarely, a vagotomy may also be performed.

**Nursing Process for the Patient Having Gastric Surgery**

**Data Collection**

Identify the patient’s fears or concerns and provide knowledge about postoperative care and discharge instructions to teach them how to assist in their recovery. This teaching includes incisional care, activity or dietary restrictions, and information about prescribed medications.

Postoperatively, the patient’s vital signs are monitored as ordered. Respiratory status is carefully monitored because

---

### TABLE 33.6 GASTRIC CANCER SUMMARY

---

**FIGURE 33.6** Subtotal gastrectomy involves removing the distal portion of the stomach. The remaining portion of the stomach is then sutured (A) to the duodenum (Billroth I procedure) or (B) to the proximal jejunum (Billroth II procedure).
the high location of the surgical incision may cause pain, which interferes with deep breathing and coughing. Atelectasis or pneumonia can develop as a result of guarding and shallow breathing. The patient’s pain is assessed and relieved, which also helps the patient’s ability to deep breathe or cough without pain. The patient’s IV site and infusion are monitored, and intake and output are recorded. The incisional site and dressings are observed for drainage and bleeding. Early ambulation is encouraged to promote a quicker recovery by improving respiratory and gastrointestinal function.

Patients may have an NG tube inserted during surgery. The drainage from the NG tube is monitored for color and amount. If bleeding or excessive amounts of drainage or abdominal distention are noted, they are reported to the physician.

**BE SAFE!**

After gastric surgery, do not irrigate or reposition an NG tube to prevent damaging the suture line.

**Complications of Gastric Surgery**

Complications that can occur after gastric surgery include hemorrhage, acute gastric distention, dumping syndrome, nutritional problems, steatorrhea (fat in stools), and pyloric obstruction.

**Hemorrhage**

The incidence of hemorrhage after gastric surgery is very low and most often caused by a dislodged clot at the surgical site or slippage of a suture. The patient experiencing hemorrhage exhibits restlessness, cold skin, increased pulse and respirations, and decreased temperature and blood pressure. The patient may have a change in level of consciousness and become confused. In addition, the patient may vomit bright red blood. To prevent aspiration during vomiting, the patient is turned to one side and the head of the bed is elevated.
Following gastric surgery, patients usually have an NG tube that has been inserted in the operating room. The drainage from the tube should be assessed for color and amount. A small amount of pink or light red drainage may be expected for the first 12 hours, but moderate or excessive bleeding should be immediately reported to the physician. The abdominal dressing should also be assessed for any drainage or bleeding.

**Gastric Distention**

In the immediate postoperative period, distention of the stomach can occur if an inserted NG tube is clogged or if an NG tube has not been inserted. Symptoms of gastric distention include an enlarged abdomen, epigastric pain, tachycardia, and hypotension. The patient may say she is feeling full and may hiccup or gag repeatedly. These symptoms must be reported to the physician.

**Critical Thinking**

**Mr. Wong**

- You are working the evening shift on a surgical unit. A patient, Mr. Wong, has had gastric surgery earlier that morning. He has an IV infusion of 1000 mL dextrose 5\% in 0.45 normal saline over 8 hours and a NG tube set to low intermittent suction. Mr. Wong is restless and reporting pain. His abdomen is distended. The suction canister contains no gastric output.

1. What nursing interventions in order of priority are needed to help Mr. Wong?
2. What equipment do you need to care for Mr. Wong?
3. As you monitor the IV, you know it is set for how many drops per minute with a 10-drop factor IV set?

Suggested answers are at the end of the chapter.

The physician usually inserts the NG tube during surgery so that the suture line is not damaged. If suction is desired, a physician’s order is required. Irrigating or repositioning the NG tube is not performed by the nurse to prevent harm to the suture line. Any problems with distention or an improperly functioning NG tube are reported to the physician. The physician may need to reposition the NG tube to correct the problem. The patient’s vital signs should be monitored until the patient’s distention is relieved and the patient is stable.

**Dumping Syndrome**

Dumping syndrome is one of the most common complications of gastric surgery. It occurs with the rapid entry of food into the jejunum without proper mixing of the food with digestive juices. On entering the jejunum, the hyperosmolar food draws extracellular fluid into the bowel from the circulating blood volume to dilute the high concentration of electrolytes and sugars. This rapid shift of fluids decreases the circulating blood volume and produces symptoms. The symptoms occur 5 to 30 minutes after eating and include dizziness, tachycardia, fainting, sweating, nausea, diarrhea, a feeling of fullness, and abdominal cramping. Additionally, the blood sugar rises, and excessive insulin is excreted in response. This release of insulin causes the patient to have symptoms of hypoglycemia about 2 hours later. Symptoms include weakness, sweating, anxiety, shakiness, confusion, and tachycardia. The patient should immediately eat some candy or drink juice containing sugar to relieve the symptoms.

The treatment for dumping syndrome includes teaching the patient to eat small, frequent meals that are high in protein and fat and low in carbohydrates, especially refined sugars (see “Nutrition Notes”). The patient is also taught to avoid fluids 1 hour before meals, with meals, or for 2 hours after meals to prevent rapid gastric emptying. It is best for the patient to lie down after meals to delay gastric emptying. The patient is told that these symptoms may last for up to 6 months after gastric surgery but usually slowly subside over time.

**Critical Thinking**

**Mrs. Lindsay**

- Mrs. Lindsay has had gastric surgery. You have taught her about dumping syndrome, and she is concerned about what she will eat. Create a 1-day meal plan for Mrs. Lindsay.

Suggested answers are at the end of the chapter.

**Nutritional Problems**

Nutritional problems that commonly occur after removal of part or all of the stomach include vitamin B\textsubscript{12} and folic acid deficiency and reduced absorption of calcium and vitamin D. Also, rapid entry of food into the bowel often results in inadequate absorption of food.

Following gastric surgery, patients may be NPO until the physician resumes a diet. IV fluid provides hydration. However, if patients are to be NPO for any length of time, they will need an alternate form of nutrition such as parenteral nutrition with an IV solution to meet their caloric and nutritional needs.

After removal of the nasogastric tube, clear fluids may be ordered with progression to full liquids, then soft foods as the patient tolerates. Foods and fluids should be introduced into the diet gradually following gastric surgery. If the patient eats too much or too fast, regurgitation may result.

**Pernicious Anemia.** Vitamin B\textsubscript{12} deficiency may occur after some or all of the stomach is removed because intrinsic factor secretion is reduced or absent. Normally vitamin B\textsubscript{12} combines with intrinsic factor to prevent its digestion in the stomach and promote its absorption in the intestines. Lifelong replacement of vitamin B\textsubscript{12} is required to prevent the development of pernicious anemia, and patients must be taught the importance of...
complying with this treatment. Traditionally after gastric surgery, it is given by the parenteral route. However, other routes such as oral tablets or nasal gel may be effectively used. Vitamin B₁₂ injections are given daily initially, then weekly, and then monthly for life. Symptoms of pernicious anemia include anemia, weakness, sore tongue, numbness and tingling, and GI upset.

**Steatorrhea**

Steatorrhea is the presence of excessive fat in the stools and is the result of rapid gastric emptying, which prevents adequate mixing of fat with pancreatic and biliary secretions. In most cases, steatorrhea can be controlled by reducing the intake of fat in the diet.

**Pyloric Obstruction**

Pyloric obstruction can occur after gastric surgery as a result of scarring, edema, inflammation, or a combination of these. The signs and symptoms are vomiting, a feeling of fullness, gastric distention, nausea after eating, loss of appetite, and weight loss. As the obstruction increases, it gradually becomes more difficult for the stomach to empty, and symptoms worsen. Conservative methods are used first, such as replacing fluids and electrolytes through IV fluids and decompressing the distended stomach using a NG tube. Surgery may be necessary if conservative measures do not relieve the signs and symptoms. Pyloroplasty widens the exit of the pylorus to improve emptying of the stomach.

---

**SUGGESTED ANSWERS TO CRITICAL THINKING**

- **Mr. Smith**
  1. Additional data would include vital signs (looking for signs of shock), assessment of Mr. Smith’s abdomen (looking for location of pain, tenderness, rigidity), assessment for any vomiting and characteristics of emesis including any blood, and assessment for IV site access.
  2. Assist Mr. Smith to a comfortable position and stay with him. Call for help. Inform the RN so the physician can be notified immediately and provide data regarding Mr. Smith’s change in condition. Administer oxygen, monitor IV fluids, and continue to monitor vital signs. Medicate for pain as ordered.
  3. Explain that you will stay with Mr. Smith as you gather data and take vital signs. State that you have informed the RN, who will assess Mr. Smith and report findings to the physician. Explain that the treatments as ordered by the physician will be started: oxygen, IV fluids, pain medication. State that explanation will be provided related to Mr. Smith’s care. Invite questions and have a nursing assistant provide Mrs. Smith with comfort needs: beverage, tissues, chair.
  4. You suspect a perforated duodenal ulcer, which is a medical-surgical emergency.
  5. RN, HCP
  6. Prepare Mr. Smith for surgery. Interventions would include maintaining NPO status, starting an IV, ensure that the consent is signed, obtain labs (may include complete blood count (CBC), chemistry panel, type and cross-match for blood), and administer antibiotics as ordered.

- **Mr. Wong**
  1. Prioritize your interventions:
     a. Take Mr. Wong’s vital signs to determine whether he is stable. Pain can sometimes increase the blood pressure and pulse rate.

---

However, gastric distention can cause pain, and once the distention is relieved, the pain caused by distention subsides.

b. Check placement of Mr. Wong’s NG tube by aspirating gastric contents and verifying the pH of the contents as ordered. It is important to check for abdominal placement of Mr. Wong’s NG tube to make sure it is not misplaced in the lungs. After abdominal placement is determined, if there is a physician’s order, the NG tube can be connected to suction equipment, usually set on low intermittent suction. Do not reposition an NG tube in a patient who has had gastric surgery. Repositioning the NG tube could damage the surgical suture line.

c. Next check the suction equipment for ordered settings and to ensure that it is turned on. The suction setting normally is ordered to be on low. A whistling sound is heard when the tube is disconnected from the suction setup. The seal should be tight on the suction canister. When the tubing is hooked to suction, gastric contents should start moving into the suction canister. It is important to make sure equipment is functioning properly to ensure patient safety.

d. Check the NG tube for clogs only if the physician orders aspiration or irrigation to be done. The tube is gently aspirated with a 60-mL catheter-tipped syringe. If the tube remains clogged, it is gently flushed as ordered with 10 to 20 mL of sterile normal saline.

e. After the gastric distention has been relieved, Mr. Wong’s pain level is reassessed to determine if he needs pain medication. Considering that he is less than 1 day postoperative, he probably needs it.

2. Necessary equipment includes stethoscope, 60-mL catheter-tipped syringe, gloves, goggles, and normal saline for irrigation.
UNIT EIGHT  Understanding the Gastrointestinal, Hepatic, and Pancreatic Systems

SUGGESTED ANSWERS TO—cont’d

3. \[
1000 \text{ mL} \times \frac{10 \text{ gtt}}{480 \text{ min}} \times \frac{1 \text{ mL}}{480 \text{ min}} = 10,000 \text{ drops} \times \frac{1}{480 \text{ min}} = 21 \text{ drops/min}
\]

Mrs. Lindsay

Although there are many variations, the following is an example of a 1-day meal plan for Mrs. Lindsay:

- **Breakfast**: one egg, any style; 1/2 orange; one glass milk
- **Snack**: one slice toast with apple butter, jelly, or jam
- **Lunch**: 2 oz ham, 1/2 cup cottage cheese, four asparagus spears
- **Snack**: 1/2 serving chicken salad on bed of lettuce
- **Dinner**: 2 oz broiled fish, 1/2 serving corn, 1/2 serving broccoli
- **Snack**: 1/2 cup yogurt or sherbet

---

REVIEW QUESTIONS

1. The nurse is planning care for a patient with an eating disorder. The patient is 40 kg and 68 inches tall. Serum laboratory data: potassium 2.6 mEq/dL, sodium 126 mEq/dL, chloride 95 mEq/dL, calcium 10.8 mg/dL. Which of these is the priority intervention for this patient?
   1. Weigh the patient daily at the same time.
   2. Maintain IV of dextrose and electrolytes.
   3. Praise intake of any type of food.
   4. Document intake and output.

2. The nurse is planning care for a team of patients. To provide care safely, for which patient should the nurse use specialized mobility equipment designed for the patient who is obese?
   1. A 25-year-old woman with body weight 5% above ideal body weight
   2. A 45-year-old man with waist-to-hip ratio measurement of 0.5
   3. A 50-year-old man with body mass index of 31
   4. A 21-year-old woman with anorexia nervosa weighing 98 pounds

3. A patient is diagnosed with aphthous stomatitis (canker sore). Which of the following actions would be appropriate?
   1. Tell patient to avoid brushing teeth until the sore has healed.
   2. Encourage patient to use a mouthwash four times a day.
   3. Apply acyclovir ointment to ease the pain of the lesion.
   4. Teach patient to apply topical tetracycline several times a day to sore.

4. The nurse is caring for a patient with gastritis. Which of the following interventions would be appropriate for a patient with acute gastritis?
   1. Monitor patient for bloody diarrhea.
   2. Explain that aspirin rarely causes gastritis.
   3. Administer phenothiazine to control vomiting.
   4. Encourage a regular diet during the acute phase of gastritis.

5. The nurse is planning a teaching session for a patient with a peptic ulcer. Which of the following would the nurse include in the teaching plan as the primary cause of peptic ulcers?
   1. Eating spicy foods
   2. A stressful life
   3. A bacterial infection
   4. Excessive caffeine intake

6. The nurse provides teaching for a patient with a peptic ulcer. Which patient statement indicates patient understanding of the purpose of H2 antagonists?
   1. Neutralize gastric acid
   2. Form a protective paste
   3. Determine gastric pH levels
   4. Inhibit secretion of gastric acid

7. A patient who has just returned from surgery after a total gastrectomy begins to vomit bright red blood. Which of the following is the priority action for the nurse to take?
   1. Increase the IV rate.
   2. Take blood pressure.
   3. Place patient onto side.
   4. Administer oxygen.
8. The nurse is teaching a patient with dumping syndrome about food choices. Which of these foods would the nurse instruct the patient to avoid?
1. Spinach and avocado salad
2. Coffee and glazed doughnut
3. Sausage and liver
4. Creamed chipped beef

9. To deliver 1000 mL of 5% dextrose in 0.45 normal saline (at 150 mL per hour using 10 drop tubings), the nurse would monitor the IV infusion at how many drops per minute? Fill in the blank.
Answer: ________________ drops per minute

Answers can be found in Appendix C.

LEARNING OUTCOMES

1. List data to collect when caring for patients with lower gastrointestinal disorders.
2. Identify the causes, signs and symptoms, and therapeutic measures of constipation and diarrhea.
3. Plan nursing care and teaching for patients with constipation or diarrhea.
4. Describe pathophysiology, therapeutic measures, nursing care, and teaching for patients with inflammatory and infectious disorders of the lower gastrointestinal tract.
5. Describe pathophysiology, therapeutic measures, nursing care, and teaching for inflammatory bowel disease.
7. Plan nursing care and teaching for patients with absorption disorders.
8. Describe causes, signs and symptoms, therapeutic measures, and nursing care for intestinal obstruction.
10. Describe causes, signs and symptoms, therapeutic measures, and nursing care for lower gastrointestinal bleeding.
11. Describe the causes, signs and symptoms, therapeutic measures, and nursing care for colon cancer.
13. Discuss how to know if nursing care for various lower gastrointestinal disorders is effective.
The lower gastrointestinal (GI) system includes the small and large intestines, rectum, and anus.

### PROBLEMS OF ELIMINATION

#### Constipation

**Pathophysiology**

Constipation occurs when the fecal mass is held in the rectal cavity for a period of time that is not usual for the patient. While the feces are held for a prolonged time in the rectum, more water is absorbed. This makes the feces drier, harder, and more difficult and sometimes painful to pass.

If a patient repeatedly ignores the urge to have a bowel movement (laxation), the musculature and rectal mucous membrane become insensitive to the presence of feces. Eventually a stronger stimulus is needed to produce the peristaltic rush required for defecation. Prolonged constipation is called obstipation.

**Etiology**

There are many causes of constipation. Medications such as narcotics, tranquilizers, and antacids with aluminum decrease motility of the large intestine and may contribute to constipation. Rectal or anal conditions such as hemorrhoids or fissures may lead to a delay in defecation because of the associated pain. Metabolic or neurologic conditions such as diabetes mellitus, multiple sclerosis, lupus erythematosus, or scleroderma may interfere with normal bowel innervation and function. Colon cancer may cause an obstruction that prevents normal bowel function and leads to constipation. Low intake of dietary fiber and fluids decreases the bulk of the feces and causes constipation. Decreased mobility, weakness, and fatigue, especially in the older adult, reduce the strength of the muscles used for defecation, increasing the likelihood of constipation.

**Prevention**

Regular exercise and a diet high in fiber and fluids are the best preventive measures for constipation. Laxatives should be used only occasionally to prevent complications.

**Signs and Symptoms**

Abdominal pain and distention, indigestion, rectal pressure, a sensation of incomplete emptying, and intestinal rumbling are indications of constipation (Table 34.1). The patient may also report headache, fatigue, decreased appetite, straining at stool, and elimination of hard, dry stool.

**Complications**

A variety of problems can result from constipation. Fecal impaction may result when the fecal mass is so dry it cannot be passed. Pressure on the colon mucosa from a mass of stool may cause ulcers to develop. Often, small amounts of liquid stool ooze around the fecal mass and cause incontinence of liquid stools. The incontinence may be treated with an antidiarrheal medication, which will worsen the constipation if a thorough assessment is not performed to rule out impaction. Straining to have a bowel movement (Valsalva’s maneuver) can result in cardiac, neurologic, and respiratory complications. If the patient has a history of heart failure, hypertension, or recent myocardial infarction, straining can lead to cardiac rupture and death. Grossly dilated loops of the colon, known as megacolon, can occur proximal to the dry fecal mass and obstruct the colon. Abdominal distention occurs, and in severe cases, loops of bowel can be palpated through the abdominal wall.

Chronic laxative abuse can lead to colonic mucosal atrophy, muscle thickening, and fibrosis. These conditions can result in perforation of the colon and necessitate an emergency colectomy.

**Diagnostic Tests**

Constipation is usually self-diagnosed or diagnosed by history and physical examination. If complications are suspected, a radiographic examination, sigmoidoscopy, and stool testing for occult blood may be needed.

**Therapeutic Measures**

Treatment of constipation depends on the cause. Fiber should be added to the diet, and exercises to strengthen abdominal muscles should be done. Behavior changes, such as setting a daily defecation time, appropriately responding to the urge to defecate, and drinking 8 oz of warm water

**WORD BUILDING**

megacolon: mega—large + colon—colon
colecotomy: col—pertaining to colon + ectomy—surgical excision
every morning and 2 to 3 L of water every day, if not contraindicated for other reasons, can help establish a more normal bowel pattern. Chronic laxative use should be discontinued. Bulk-forming agents such as psyllium (Metamucil) or stool softeners such as docusate sodium (Colace) should be used instead of laxatives. Enemas and rectal suppositories are used only in extreme cases and are discontinued when an acute episode is resolved. Methylnaltrexone (Relistor) given subcutaneously treats opioid-induced constipation for patients receiving palliative care when other laxatives have not been effective. It does not treat other forms of constipation.

**Nursing Process for the Patient With Constipation**

**DATA COLLECTION.** The patient may feel self-conscious or embarrassed when interviewed about bowel habits and history. Consideration should be given to the patient’s feelings by postponing the discussion until rapport has been established. Data gathered in privacy should include the onset and duration of constipation, past elimination pattern, current elimination pattern, occupation, lifestyle (stress, exercise, nutrition), history of laxative or enema use, medical-surgical history, and current medications being taken. Color, consistency, and any odor of the stool, as well as any intestinal symptoms, are also important.

After the interview, the patient’s abdomen is inspected and palpated for distention and symmetry. Inspection of the perianal area may reveal fissures, external hemorrhoids, or irritation.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

**Constipation related to irregular defecation habits**

**EXPECTED OUTCOME:** The patient will maintain passage of soft, formed stool every 1 to 3 days without straining.

- Assess normal pattern of defecation, diet and fluid intake, medications, surgeries, and use of laxatives to help identify factors contributing to constipation.
- Determine patient’s access to the bathroom and ability to use the toilet to ensure barriers to safe toileting, such as unsafe obstructing furniture arrangements or clutter, are removed.
- Set a specific time for defecation, such as after a meal, to facilitate the urge reflex.
- Place feet on a footstool to promote flexion of the hips, which aids defecation.
- Provide a high-fiber, high-residue diet including fresh fruits, vegetables, and whole grains with 2 g of bran added to cereal daily for constipation caused by decreased motility and muscle tone or a low-fiber diet to significantly increase bowel movements and decrease the number of laxatives, enemas, or stool softeners required (“Nutrition Notes”).
- Increase fluid if not contraindicated to 2 to 3 L per day to aid in ability to discontinue laxative use.
- Increase activity through a daily walking program and abdominal exercises designed to improve the muscle tone to improve peristalsis and promote more spontaneous defecation.

### Nutrition Notes

**Treating Constipation With Food Formula**

Constipation may be successfully treated with 1 to 2 oz of the following mixture taken with the evening meal:

- 1 cup applesauce,
- 1 cup All-Bran cereal, and
- 1/2 cup 100% prune juice.

Mixture may be stored in the refrigerator for 5 days and then should be discarded. In all cases of constipation, especially when increased fiber is given, adequate fluid intake is essential.

**Treating Constipation With Food Choices**

Achieving the recommended fiber intake of 21 to 38 grams per day is a matter of prudent choices at every meal. Listed below are examples of high fiber foods on the left and foods in the same category on the right with less fiber.

Many other foods also contribute to fiber intake and can be evaluated via nutrition labels or at [http://ndb.nal.usda.gov](http://ndb.nal.usda.gov) or [http://nutritiondata.self.com](http://nutritiondata.self.com). Individuals who wish to correct constipation without medications should determine their present fiber intake and increase it gradually to the U.S. Department of Agriculture Recommended Dietary Allowance while also drinking sufficient water.
Diarrhea occurs when fecal matter passes through the intestine rapidly, resulting in decreased absorption of water, electrolytes, and nutrients and causing frequent, watery stools. Classification and severity of diarrhea are based on the number of unformed stools in 24 hours.

Pathophysiology and Etiology
The most common cause of acute diarrhea is a bacterial or viral infection. Bacteria (normal flora) are normally found in the intestines. If these bacteria grow out of control or if bacteria or viruses are ingested in contaminated food or water, infection results. Some bacteria release toxins that irritate the intestinal mucosa, causing an inflammatory response and an increase in mucus production. Hyperperistalsis occurs, which lasts until the irritants have been excreted. The most common infectious agents are Escherichia coli, Campylobacter jejuni, Shigella spp., Clostridium difficile, Giardia spp., and Salmonella spp.

Poor tolerance or allergies to certain foods may cause diarrhea. Foods that most commonly cause diarrhea are additives (such as nutmeg or sorbitol), caffeine, milk products, meats, wheat, and potatoes. Acute diarrhea usually resolves in 7 to 14 days.

Chronic diarrhea may result from inflammatory disease, osmotic agents, excessive secretion of electrolytes, or increased intestinal motility. Infectious diseases such as Crohn’s disease or ulcerative colitis (discussed later) may impair absorption, resulting in frequent, watery stools. Osmotic diarrhea results from ingestion of laxatives or other agents that prevent absorption of water or nutrients in the intestine. Additional causes of malabsorption include surgical resection or disease of certain areas of the intestinal tract, such as the terminal ileum or pylorus. Radiation therapy for cancer also may induce a malabsorption syndrome. Enteral feedings can result in diarrhea, especially when malnutrition has caused edema in the gut wall, which decreases absorption.

Increased secretion of water and electrolytes by the intestinal mucosa associated with certain hormonal disorders results in high-volume fecal output. An irritable bowel or a neurologic disorder may cause increased motility problems.

Prevention
To prevent diarrhea, proper handling, storage, and refrigeration of all fresh foods helps to minimize contact with infectious agents. Milk and milk products must be kept refrigerated and protected. Hand hygiene and cleaning of the kitchen and the food preparation and serving items are extremely important. Also, enteral feedings should be given using full-strength formula rather than diluting the formula. This reduces the risk of contaminating the formula.

Signs and Symptoms
Initial diarrhea stools may be foul smelling and have undigested food particles and mucus (Table 34.3). The stools may also contain blood or pus. Diarrhea resulting from food poisoning usually has an explosive onset and may be accompanied by nausea and vomiting. Abdominal cramping, distention, anorexia, intestinal rumbling, and thirst are common. Fever indicates infection. Weakness and dehydration from fluid loss may occur (“Gerontological Issues”).

### TABLE 34.2 CRITERIA FOR REGULAR BOWEL FUNCTION

| 1. A regular time for defecation is routine. |
| 2. A regular exercise program is followed. |
| 3. Laxative use is avoided. |
| 4. Water consumption is 2–3 L per day. |
| 5. High-fiber and high-residue foods are added to the diet. |
| 6. Consistency of stools reported is soft and formed. |
| 7. Frequency of stools is every 1 to 3 days. |
Diagnostic Tests

The diagnosis of diarrhea is determined by the onset and progression of the condition, presence of fever, laboratory examinations, and visual inspection of the stool for bacteria, pus, or blood. Diarrhea mixed with red blood cells (RBCs) and mucus is associated with cholera, typhoid, typhus, large-bowel cancer, or amebiasis. Diarrhea mixed with white blood cells (WBCs) and mucus is associated with shigellosis, intestinal tuberculosis, salmonellosis, regional enteritis, or ulcerative colitis. Bulky, frothy stool is seen in celiac disease. Pasty stools usually have a high fat content and may be associated with common bile duct obstruction and celiac disease.

Therapeutic Measures

Replacing fluids and electrolytes is the first priority. This can be done by increasing oral fluid intake and using solutions with glucose and electrolytes if ordered by the healthcare provider (HCP). Intravenous (IV) fluid replacement may be necessary for rapid hydration, especially in the very young or very old. An elimination diet can be tried to identify foods that may contribute to diarrhea. Foods known to cause diarrhea are eliminated to see if a change in bowel function occurs. Each food item is then added back into the diet, one at a time, to see which ones cause diarrhea.

If the patient has three or more watery stools per day, motility of the intestines can be decreased with the use of drugs, such as diphenoxylate (Lomotil), difenoxin HCl (Motofen), and loperamide (Imodium). If diarrhea is thought to be caused by antibiotics that change the normal flora of the bowel, a Lactobacillus granule probiotic supplement (Lactinex) may be used to help restore the normal flora. Fecal transplant can restore the normal intestinal flora in those who are ill (Chapter 32). Antimicrobial agents are prescribed if infectious agents have been identified.

Nursing Process for the Patient With Diarrhea

Data Collection. Observation of the patient’s behaviors and symptoms assists in identifying the cause of diarrhea. Ask the patient to describe any symptoms, when they started, and how long they have been present. Questions should include “Is there any abdominal pain, urgency, or cramping?” and “What time of the day does it happen?” Stool consistency, color, odor, and frequency are documented.

Observe for symptoms of dehydration, such as tachycardia, hypotension, decreased skin turgor, weakness, thready pulse, dry mucous membranes, and oliguria. Obtain the patient’s height and weight to establish a baseline. Abnormal laboratory studies that may indicate dehydration include increased serum osmolality, increased specific gravity of urine, and increased hematocrit. Decreased serum potassium may result from intestinal loss of potassium.

Inspect the abdomen for distention. The patient’s usual dietary habits and any changes or recent exposure to contaminated...
Food or water are noted. Determine if medications such as antibiotics or laxatives could have contributed to the diarrhea. If the patient has recently traveled, determine the geographic location and whether exposure to an infected person or someone with similar symptoms occurred.

Data are collected on the patient’s coping mechanisms for use if the patient needs to express concerns or anxiety regarding incontinence of liquid stools and embarrassment.

**Nursing Diagnoses, Planning, and Implementation.**

**Diarrhea related to infection or possible ingestion of irritating foods**

**Expected Outcome.** The patient will maintain formed, soft stool every 1 to 3 days.

- Obtain history including medications regarding diarrhea episode to help identify cause.
- Monitor and record stool characteristics, amount, and frequency to plan care.
- Ensure hand hygiene by patient, family, and health care staff to prevent the spread of infection.
- Identify potentially infected persons or contaminated foods to prevent the spread of infection.
- Consider private patient room to prevent infection transmission.
- Maintain nothing by mouth (NPO) as ordered to promote bowel rest.
- Give antidiarrheal medications as ordered. Controlling diarrhea controls comfort and fluid balance.
- Keep skin clean, dry, and protected with a moisture barrier, such as petrolatum or medicated ointment, after each bowel movement or use a fecal incontinence appliance to protect perianal skin from contact with liquid stools and their enzymes (see “Evidence-Based Practice”).
- Provide clear liquids, such as water, juices, bouillon, and gelatin, with progression to a low-residue diet when the acute diarrhea phase is over (“Nutrition Notes”).
- Limit caffeine intake because it stimulates intestinal motility.

**Risk for Deficient Fluid Volume related to frequent passage of stools and insufficient fluid intake**

**Expected Outcome.** The patient will maintain a stable weight and vital signs, and urine output will remain within normal limits at all times.

- Record intake and output (including diarrheal stools) to determine fluid balance.
- Weigh patient daily to determine fluid loss.
- Maintain IV fluid replacement as ordered to maintain fluid balance if output is greater than intake.
- Encourage fluids when acute diarrhea subsides to maintain fluid balance.
- Teach patient signs and symptoms of dehydration to report to allow prompt treatment.

**Evaluation.** Goals have been met if frequency of diarrheal stools is decreased and balance of fluid and electrolytes is achieved.

---

**Nutrition Notes**

**Deciding When to Refer an Adult With Diarrhea for Medical Care**

Most instances of diarrhea in healthy adults are self-limiting and resolve without treatment. Indications for medical consultation include the following:

- Lasts for more than 3 days
- Causes severe pain in the abdomen or rectum
- Provokes a fever of 102°F or higher
- Produces blood in the stool or black, tarry stools
- Is accompanied by signs of dehydration
- Occurs in a person with medical conditions for which fasting, dehydration, or infectious disease is a hazard

Healthy adults at minimal risk of electrolyte imbalance may institute self-treatment as follows:

- **For the first 12 hours:** Water or oral rehydration solutions at room temperature. Easily absorbed fluids maintain hydration. Hot or cold liquids are more likely to stimulate peristalsis.
- **For the second 12 hours:** Clear liquids, no caffeine or extremes of temperature. If more than 5% of body weight is lost, seek medical attention.
- **For the third 12 hours:** Full liquids. Experiment with milk in case temporary lactose intolerance has developed as a result of intestinal inflammation.
- **For the fourth 12 hours:** Soft diet. Include applesauce or banana for pectin and also rice, pasta, and bread without fat (digested by enzymes usually unaffected in gastroenteritis).
- **By the 48th hour:** Regular diet. If diarrhea has not resolved and regular diet is not tolerated, seek medical treatment.

**Inflammatory and Infectious Disorders**

Many diseases of the lower GI tract are a result of inflammation in the bowel. Sometimes the inflamed areas become infected, resulting in a worsening of symptoms.

**Appendicitis**

**Pathophysiology**

Appendicitis is the inflammation of the appendix, the small, finger-like appendage attached to the cecum of the large intestine (see Fig. 32.1). Because of the small size of the appendix, obstruction may occur, causing inflammation and making it susceptible to infection.

**Signs and Symptoms**

Signs and symptoms of appendicitis include fever, increased WBCs, and generalized pain in the upper abdomen. Within
hours of onset, the pain usually becomes localized to the right lower quadrant at McBurney’s point, midway between the umbilicus and the right iliac crest (Fig. 34.1). This is one of the classic symptoms of appendicitis. Nausea, vomiting, and anorexia are also usually present.

Physical examination reveals slight abdominal muscular rigidity (guarding), normal bowel sounds, and local rebound tenderness (intensification of pain when pressure is released after palpation) in the right lower quadrant of the abdomen. Sometimes there is pain in the right lower quadrant when the left lower quadrant is palpated (Rovsing’s sign). The patient may keep the right leg flexed for comfort and experience increased pain if the leg is straightened.

Diagnostic Tests
A complete blood cell count (CBC) reveals elevated leukocyte (WBC) and neutrophil counts. An ultrasound or computed tomography (CT) scan reveals an enlargement in the area of the cecum.

Therapeutic Measures
The patient is kept NPO, and surgery is done immediately unless there is evidence of perforation or peritonitis. Applying ice to the site of pain and keeping the patient in a semi-Fowler’s position may help reduce pain while the diagnosis is being made.

Laxatives and enemas are avoided because they may cause or complicate a rupture. The use of a heating pad on the abdomen is avoided because the warmth may increase inflammation and risk of rupture. If the appendix has ruptured, IV fluids and antibiotic therapy are started to treat infection and peritonitis. Surgery may or may not be done right away. If infection is present, a drain may be inserted into the abdomen by a radiologist. Surgery may then be delayed for up to several weeks while the infection is resolved.

After surgery, the diet is advanced as ordered and tolerated. If the appendix has ruptured, the patient may have an orogastric or nasogastric (NG) tube to decompress the stomach. Vital signs and abdominal data are collected to monitor for signs and symptoms of peritonitis. Pain control to promote early ambulation, coughing, deep breathing, and movement help prevent respiratory complications.

Complications
Perforation, abscess of the appendix, and peritonitis are major complications of appendicitis. With perforation, the pain is severe, and temperature is elevated to at least 100°F (37.7°C). An abscess is a localized collection of pus separated from the peritoneal cavity by the omentum or small bowel. This is usually treated with IV antibiotics and surgical drainage. An appendectomy is done about 6 weeks later.
**Peritonitis**

Peritonitis is inflammation of the peritoneum that occurs from a variety of causes. It is a serious condition that can be life threatening.

**Pathophysiology and Etiology**

Trauma, ischemia, or tumor perforation in any abdominal organ causes leakage of the organ’s contents into the peritoneal cavity. The most common cause of peritonitis is a ruptured appendix, but it can also occur after perforation of a peptic ulcer, gangrenous gallbladder, intestinal diverticula, incarcerated hernia, or gangrenous small bowel. It may also be a complication of peritoneal dialysis. Peritonitis results from the inflammation or infection that is caused by the leakage. The tissues become edematous and begin leaking fluid containing increasing amounts of blood, protein, cellular debris, and WBCs. Initially, the intestinal tract responds with hypermotility, but this is soon followed by paralysis (paralytic ileus).

**Signs and Symptoms**

Generalized abdominal pain evolves into localized pain at the site of the perforation or leakage. The area of the abdomen that is affected is extremely tender and aggravated by movement. Rebound tenderness and abdominal rigidity are present. Decreased peristalsis results in nausea and vomiting. Infection causes fever, increased WBCs, and an elevated pulse.

**Diagnostic Tests**

Rapid diagnosis is essential in preventing complications. Tests include an abdominal x-ray or computed tomography (CT) scan to show distention or perforation, WBCs significantly elevated, paracentesis and laboratory studies to identify a causative organism, or exploratory surgery to identify the cause.

**Therapeutic Measures**

The patient is NPO because of impaired peristalsis. Fluid and electrolyte replacement is crucial to correct hypovolemia and prevent or treat shock. Abdominal distention is relieved through insertion of an orogastric (or NG) tube with low intermittent suction. Antibiotics are used to treat or prevent sepsis. Depending on the cause of the peritonitis, surgery may be performed to excise, drain, or repair the cause. An ostomy may be formed to divert stool, allowing resolution of the infection. After surgery, the patient usually has a wound drain, a NG tube, and a urinary catheter. Pain control is essential to overall recovery. Severely compromised patients may receive parenteral nutrition (PN) to meet nutritional needs.

**Complications**

Wound dehiscence (separation of layers of a surgical wound) or evisceration (protrusion of abdominal viscera) can occur if the patient has had abdominal surgery. Complications of peritonitis are intestinal obstruction (discussed later), hypovolemia caused by the shift of fluid into the abdomen, and septicemia from bacteria entering the bloodstream. Shock and ultimately death may result.

---

**Diverticulosis and Diverticulitis**

**Pathophysiology**

A diverticulum is a herniation or outpouching of the bowel mucous membrane caused by increased pressure within the colon and weakness in the bowel wall. Diverticulosis is a condition in which multiple diverticula are present without evidence of inflammation (Fig. 34.2). Many people have diverticulosis without knowing it because it develops gradually. When food and bacteria are trapped in a diverticulum, inflammation and infection develop. This is called diverticulitis.

**Etiology**

Chronic constipation usually precedes the development of diverticulosis by many years. When the patient is chronically constipated, pressure within the bowel is increased, leading to development of diverticula. A major cause of the disease is a decreased intake of dietary fiber. Diverticulosis is most common in the sigmoid colon. A small percentage of patients with diverticulosis develop diverticulitis. People older than age 60 are the most common group to experience diverticulitis.

---

**FIGURE 34.2** A diverticulum is a herniation or outpouching of the bowel mucous membrane. Having multiple diverticula is a condition called diverticulosis. If they become inflamed or infected, the condition is called diverticulitis.
**Prevention**

Diverticulitis can be prevented by increasing dietary fiber to prevent constipation and onset of diverticulosis.

**Signs and Symptoms**

The patient with diverticulosis is generally asymptomatic. When diverticulitis is present, the patient exhibits bowel changes, possibly alternating between constipation and diarrhea (Table 34.4). Steady or crampy pain in the left lower quadrant of the abdomen is the most common symptom. As the condition worsens, bleeding may occur, along with weakness, fever, fatigue, and anemia. Guarding and rebound tenderness may be present. If an abscess develops, the diverticulum may rupture, leading to peritonitis (“Gerontological Issues”).

**Diagnostic Tests**

Diverticulosis is confirmed with sigmoidoscopy, colonoscopy, or barium enema. The diverticula and specific areas of inflammation can be seen during a colonoscopy or sigmoidoscopy. If an abscess is suspected, a CT scan may be done. Barium enema may show irregular narrowing of the colon and thickened muscle walls. A stool specimen may show occult blood. An abdominal x-ray examination may be done to identify a perforated diverticulum.

**Therapeutic Measures**

Diverticulosis is managed by preventing constipation. With acute diverticulitis, the patient may be hospitalized for administration of IV antibiotics and pain control. An NG tube, IV fluids, and NPO status may be ordered until pain, nausea or vomiting, fever, and inflammation decrease. When the acute period is over, a progressive diet is started. Whether or not perforation occurs, surgical resection with anastomosis or a temporary colostomy (discussed later) may be done to allow the inflammation to subside and the diseased portion of the colon to rest.

Dietary considerations for a patient with diverticulosis (without evidence of inflammation) include foods that are soft but high in fiber, such as prunes, raisins, and peas. Unprocessed bran can be added to soups, cereals, and salads to give added bulk to the diet. Fiber should be increased in the diet slowly to prevent excess gas and cramping. Some health care providers recommend avoiding nuts or foods with small seeds that can get caught in diverticula, such as tomatoes and raspberries, but this has not been shown to prevent diverticulitis. If the patient is overweight, he or she is encouraged to lose weight.

Surgery may be needed for ruptured diverticula. Laparoscopic surgery can be used to decrease the morbidity and mortality associated with this emergency surgery.

**Nursing Process for the Patient With an Inflammatory or Infectious Disorder**

**Data Collection**

Assessment of pain is essential for patients with inflammation or infection. Monitor the patient closely and notify the HCP immediately if pain increases, especially if associated with abdominal rigidity. Increased pain may indicate that the bowel has ruptured and peritonitis is developing. Abdominal distention is monitored and recorded. With diverticulitis, a firm mass may be palpated in the sigmoid area.

Vital signs are monitored for fever or signs of septic shock. Intake and output are monitored and recorded accurately so that appropriate fluid replacement therapy is ordered. Monitoring for reduced urinary output, dropping blood pressure, and rising pulse rate can show fluid volume imbalance. If a fever is noted, the patient may be developing sepsis. All symptoms are reported to the HCP promptly.

**Gerontological Issues**

With aging, the incidence of diverticular disease increases. Clinical manifestation of this condition may include abdominal pain, rectal bleeding, nausea, and vomiting. Patients may not notice the abdominal pain until infection is present. Many times the symptoms are not reported early because patients fear it may be cancer. Blood in the stool, which can be an indication of diverticulitis, may not be seen by the older adult due to impaired vision.
Nursing Diagnoses, Planning, and Implementation

**Acute Pain related to inflammatory process**

**EXPECTED OUTCOME**: The patient will report pain is at an acceptable level within 30 minutes of report of pain.

- Have patient rate pain on objective scale such as 0 to 10 to determine pain level.
- Give analgesics or antispasmodic drugs as ordered to relieve pain.
- Use position changes, diversion, and relaxation exercises to help relieve pain. Semi-Fowler’s position may reduce tension on the abdomen.
- Provide frequent mouth care if an NG tube is in place to increase comfort.

**Risk for Deficient Fluid Volume related to diarrhea or fluid shifting from the circulation to the peritoneal cavity**

**EXPECTED OUTCOME**: The patient will maintain vital signs and urine output within normal limits at all times.

- Record intake and output to determine fluid balance.
- Weigh patient daily to determine fluid loss.
- Monitor vital signs and urine output and report changes to detect changes from within normal limits.
- Maintain IV fluid replacement as ordered to maintain fluid balance if output is greater than intake.

For constipation related to a low-fiber diet, see the earlier section on constipation.

**Evaluation**

The goals are met if the patient reports that pain is controlled, vital signs and urinary output are stable, and patient has regular, comfortable bowel elimination.

**INFLAMMATORY BOWEL DISEASE**

**Crohn’s Disease**

**Pathophysiology**

Crohn’s disease is an inflammatory bowel disease (IBD) that can involve any part of the GI tract but most commonly affects the terminal portion of the ileum, or first part of the large intestine. The inflammation extends through the intestinal mucosa, which leads to the formation of abscesses, **fistulas** (abnormal connections between structures), and fissures (unnatural tracts or ulcers). The inflamed areas from Crohn’s disease can alternate with areas of healthy tissue, so the inflamed areas are referred to as “skip lesions” (because they are not continuous lesions along the intestine). As the disease progresses, obstruction occurs because the intestinal lumen narrows with inflamed mucosa and scar tissue.

**Etiology**

Although the exact cause of Crohn’s disease has not been identified, it tends to occur within families. Other possible influences are autoimmune processes and infectious agents. Crohn’s disease is most often diagnosed between the ages of 15 and 30 and occurs more often in women than men. Smoking increases the risk for Crohn’s disease. The patient experiences periods of remissions and exacerbations. Physical or psychological stress may trigger exacerbations (“Cultural Considerations”).

**Signs and Symptoms**

Crampy abdominal pains (unrelieved by defection), weight loss, fever, and diarrhea occur. Because the crampy pains occur after eating, the patient often does not eat to avoid the pain. A lack of eating and poor absorption of nutrients results in weight loss and malnutrition. Chronic diarrhea contributes to fluid deficit and electrolyte imbalance. The inflamed intestine may perforate, leading to the formation of intra-abdominal or anal fissures, abscesses, or fistulas. Symptoms outside the GI tract, such as arthritis, skin lesions, and inflammatory disorders of the eyes, and abnormalities of liver function may also occur.

**Complications**

In addition to malnutrition, the development of fissures, abscesses, strictures, or fistulas is the most common complication of Crohn’s disease. Fistulas may include entero vaginal (small bowel to vagina), enterovesical (small bowel to bladder), enterocutaneous (small bowel to skin), enterointerocutaneous (small bowel to small bowel), or enterocolonic (small bowel to colon) (Fig. 34.3). Fistulas communicating with organs that then drain externally can cause tremendous skin irritation, as well as increased risk of developing infections. Fistulas are corrected surgically and antibiotics may be used.

**Diagnostic Tests**

Laboratory testing looks for anemia, infection, liver function, low albumin due to poor absorption of protein, and stool infections or occult blood. Endoscopy (colonoscopy and sigmoidoscopy), with multiple biopsies of the diseased colon and terminal ileum, is used to diagnose Crohn’s disease. Other endoscopic tests include capsule endoscopy (swallowed camera the size of a pill), ultrasound to identify fistulas and areas of bleeding, and double balloon enteroscopy, which

---

**Cultural Considerations**

Ulcerative colitis and Crohn’s disease are more common in Caucasians, persons of Jewish descent, and upper-middle-class urban populations. The incidence of Crohn’s disease is increasing rapidly in western Europe and North America. These findings support possible hereditary or environmental risk factors for inflammatory bowel disease.
provides views of the inside of tissue folds. Crohn’s disease is confirmed by granulomas in the biopsy specimen. Imaging tests include multiphase CT enterography and magnetic resonance enterography (MRE), which provide detailed images of the intestines.

**Therapeutic Measures**

Management of Crohn’s disease is aimed at achieving remission and maintaining it because there is no cure. Symptoms are controlled by reducing the intestinal inflammation that is the underlying cause of the symptoms. The classes of medications used to achieve these goals are aminosalicylates, biologics, corticosteroids, and immunomodulators (Table 34.5). Treatment is individualized. Aminosalicylates reduce inflammation and have various formulations to be delivered to specific sites in the intestines. They do not prevent acute episodes. Biologics selectively target agents in the inflammatory process to block their action and effects. Corticosteroids are used during an acute inflammation, then tapered and discontinued. Budesonide (Entocort EC), an anti-inflammatory synthetic corticosteroid, acts locally rather than affecting the whole body. Immunomodulators modify the immune system to decrease inflammation. They may be used with steroids to treat acute episodes because they have a longer onset of action. Traditionally, corticosteroids, then azathioprine, then infliximab, which inhibits tumor necrosis factor, a primary cause of the inflammation, are given.

</tr>
</tbody>
</table>
Antidiarrheal medications such as diphenoxylate with atropine (Lomotil) or loperamide (Imodium) are used. Bulk-forming laxatives may help reduce loose stools and subsequently skin irritation.

As complications develop, surgery may be indicated for obstruction, stricture, fistula, abscess, excessive bleeding, perforation, toxic megacolon (loss of muscle tone and dilation in colon), or symptoms that do not respond to treatment. Surgery does not cure Crohn’s disease because it can recur elsewhere in the GI tract. Surgical procedures include strictureplasty to widen areas of stricture, resection of the affected area with anastomosis, colectomy with ileorectal anastomosis, or proctocolectomy (rectum and colon) with ileostomy. See details regarding intestinal ostomies later in this chapter. A Kock pouch is not recommended for those with Crohn’s disease because the disease may affect the pouch.

A healthy diet is important in overall health, but there is no special diet for Crohn’s disease. A dietitian referral is important for nutritional support. Malnutrition is a concern if the small intestine is affected and nutrients are not absorbed properly. Folic acid and vitamin B12 supplements may be needed. Calcium intake may be decreased and osteoporosis is a concern. Calcium 1500 mg daily and vitamin D supplements are considered. Foods that increase symptoms should be avoided. Enteral feedings may be required and can be done at night through a gastrostomy tube (G tube) or nasogastric feeding tube. For acute flare-ups, PN may be used to rest the GI tract. Adequate fluid intake is essential to prevent dehydration if diarrhea is present.

Nursing Process for the Patient With Crohn’s Disease

Because of the similarities between Crohn’s disease and ulcerative colitis, the nursing processes for both are discussed together in the “Nursing Process for the Patient with Inflammatory Bowel Disease” section that follows.

Ulcerative Colitis

Pathophysiology

Ulcerative colitis is similar to Crohn’s disease. Crohn’s disease, however, can occur anywhere in the GI system, whereas ulcerative colitis occurs in the large colon and rectum. Multiple ulcers and diffuse inflammation occur in the superficial mucosa and submucosa of the colon. The lesions spread in a continuous pattern throughout the large intestine and usually involve the rectum.

Etiology

Infection, allergy, and autoimmune response are possible causes of ulcerative colitis. Environmental agents such as...

**Signs and Symptoms**

Abdominal pain, diarrhea, rectal bleeding, and fecal urgency are common symptoms of ulcerative colitis (Table 34.6). Anorexia, weight loss, cramping, vomiting, fever, and dehydration associated with passing 5 to 20 liquid stools a day may also occur. Along with the potential for fluid and electrolyte imbalance, calcium is lost. Anemia often develops as a result of rectal bleeding. Serum albumin level may be low because of malabsorption. Like Crohn’s disease, arthritis, skin lesions, inflammatory disorders of the eyes, and abnormalities of liver function may also occur. Symptoms are usually intermittent, with remissions lasting from weeks to years.

**Complications**

Malnutrition occurs less often with ulcerative colitis than with Crohn’s disease. Other complications include the potential for hemorrhage during an acute phase, bowel obstruction, perforation, and peritonitis. The risk for colorectal cancer is also increased in patients with ulcerative colitis.

**Diagnostic Tests**

Anemia and infection are checked with blood tests. Anemia is often present because of blood loss. Examination of stool specimens is done to rule out the presence of any bacterial or amebic organisms. The stool is positive for blood in the presence of ulcerative colitis. Electrolytes may be depleted from chronic diarrhea. There is protein loss because of liver dysfunction and malabsorption. Barium enema is an x-ray with contrast that looks at the lower GI tract. A flexible sigmoidoscopy to view the lower colon or a colonoscopy to see the whole colon is done. Biopsy specimens show inflamed cells. Leukocyte scintigraphy, a noninvasive imaging test, uses the patient’s white blood cells tagged with a radioactive material to detect infection and inflammation in the colon.

**Therapeutic Measures**

Diet and lifestyle changes and then medications are used for treatment. Foods that cause gas or diarrhea should be avoided. Because the offending foods may be different for each patient, foods are tried in small amounts if they are thought to cause symptoms. In general, high-fiber foods, caffeine, spicy foods, and milk products are avoided. Parenteral nutrition may be needed to meet nutritional needs during acute exacerbations. Diarrhea may increase the need for fluids to prevent dehydration.

Many of the medication classes used with Crohn’s disease are used for ulcerative colitis (see Table 34.5). Surgery is considered for excessive bleeding, severe symptoms, perforation, or toxic megacolon. Because ulcerative colitis usually involves the entire large intestine, surgery removes the entire colon and rectum. An ileoanal pouch (restorative proctocolectomy) or proctocolectomy with ileostomy (discussed later) are the procedures done. Sugery cures ulcerative colitis if the colon is removed.

An ileoanal pouch does not require an ostomy pouch to be worn and is the more common surgery performed. Because the anus and sphincter are saved, stool still passes through the anus. The rectum and colon are removed and the end of the ileum, which is made into a J-shaped pouch, is attached to the anus. A temporary ileostomy is created to allow the pouch to heal. After about 12 weeks, the ileostomy is closed. Several bowel movements per day occur. The stool is of soft consistency. Surgical complications can include a bowel obstruction, or an inflammation of the pouch (pouchitis), which is treated with antibiotics.

**Nursing Process for the Patient With Inflammatory Bowel Disease**

**Data Collection**

A history obtained from the patient includes symptoms, including the onset, duration, frequency, and severity. Ask if there has been any correlation between exacerbations of symptoms related to dietary changes or stress. Determine the presence of any food allergies or intolerances that may increase diarrhea. Also, note the daily and weekly intake of...
Chapter 34  Nursing Care of Patients With Lower Gastrointestinal Disorders 757

caffeine, nicotine, and alcohol because all these stimulate the bowel and can cause cramping and diarrhea. Assess the patient for nutritional status and signs of dehydration. Ten to 20 pounds can be lost in a 2-month period. Perianal skin should be assessed for irritation and excoriation. Assessment of emotional status, coping skills, and verbal and nonverbal behaviors is essential. The patient may withdraw from family and friends because of frequent bowel movements. Anxiety, sleep disturbances, depression, and denial can be problems. If surgery involving an ileostomy is planned, the patient is at risk for altered body image.

Nursing Diagnoses, Planning, and Implementation

Acute Pain related to increased peristalsis and cramping

**EXPECTED OUTCOME** The patient will state pain is relieved or at an acceptable level within 30 minutes of report of pain.

- Have patient rate pain on objective scale such as 0 to 10 to determine pain level.
- Document the character of the pain (dull, cramping, burning) and ask whether the pain is associated with meals or other activities to plan care.
- Give analgesics and medications to relieve cramping, as prescribed.

Diarrhea related to the inflammatory process

**EXPECTED OUTCOME** The patient will maintain formed, soft stool every 1 to 3 days.

- Document characteristics of stools, including color, consistency, amount, frequency, and odor to plan care.
- Ensure patient has quick access to the bathroom or provide a bedside commode to prevent incontinence.
- Administer antidiarrheal medication as prescribed. Controlling diarrhea controls comfort and fluid balance.
- Encourage bed rest to decrease peristalsis.
- Keep the environment clean and odor free to help alleviate anxiety.
- Teach the patient to avoid high-fiber foods such as whole grains and raw fruits and vegetables, as well as caffeine, alcohol, and nicotine because they stimulate intestinal motility.

Risk for Deficient Fluid Volume related to diarrhea and insufficient fluid intake

**EXPECTED OUTCOME** The patient will maintain vital signs and urine output within normal limits at all times.

- Weigh patient daily to determine fluid loss.
- Record intake and output (including diarrhea stools) to determine fluid balance.
- Document and report signs of deficient fluid volume to the HCP to allow treatment.
- Maintain IV fluids as ordered to maintain fluid balance.
- Encourage fluids when acute diarrhea subsides to maintain fluid balance.
- Teach patient signs and symptoms of dehydration to report to allow prompt treatment.

Anxiety related to symptoms and frequency of stools and treatment

**EXPECTED OUTCOME** The patient will report that anxiety is reduced.

- Answer questions; talk in a calm, confident manner; and actively listen to the patient to reduce anxiety, which aggravates symptoms of inflammatory bowel disease.

Impaired Skin Integrity related to frequent loose stools

**EXPECTED OUTCOME** The patient’s skin will remain intact at all times.

- Keep perianal skin clean, dry, and protected with a moisture barrier, such as petrolatum or medicated ointment, after each bowel movement to protect perianal skin from contact with liquid stools and their enzymes.
- Provide sitz baths, which may be comforting and helpful in keeping skin clean to prevent excoriation.

Imbalanced Nutrition: Less Than Body Requirements related to malabsorption

**EXPECTED OUTCOME** The patient will maintain weight within normal range for height and age.

- Weigh weekly to detect weight loss.
- Give special liquid (elemental) formula that is absorbed in the upper bowel as ordered to allow the colon to rest.
- Maintain PN as ordered to provide nourishment if the patient is unable to tolerate oral intake.

See the “Nursing Care Plan for the Patient With Inflammatory Bowel Disease.”

Evaluation

Goals have been met if pain is relieved, frequency of diarrhea stools is decreased, fluid and electrolyte balance is achieved, anxiety is reduced, skin is intact, and weight is within normal range for height and age.

IRRITABLE BOWEL SYNDROME

Pathophysiology

Irritable bowel syndrome (IBS) is not a disease but rather a functional problem. The colon mucosa is not damaged by the condition, and there is no increased risk of colorectal cancer. IBS is a disorder of altered intestinal motility in which the colon muscle contracts more easily. It contracts in a disorderly way that can be violent and last for long times or, at times, it may not contract at all. The abnormal contractions lead to changes in bowel patterns. Thus, the disorder may be classified as IBS with diarrhea, IBS with constipation, or IBS with mixed diarrhea and constipation. Additionally, patients experience increased abdominal discomfort or pain. Localized prolonged contractions may cause stool to be retained for a long time, causing it to become hardened as water is absorbed from it. Bloating may also occur because air is unable to be expelled. Mucus may be seen in the stool, although this
CRITICAL THINKING

Judy Moore

Judy Moore is an 18-year-old college student who has just been diagnosed with Crohn’s disease.

1. What questions should the nurse ask Judy to identify her symptoms?
2. What nursing diagnoses would be relevant for Judy’s condition?
3. What patient-centered care can help Judy adapt to this disease?
4. If Judy’s condition were to worsen, what manifestations would be exhibited?
5. What members of the health team might the nurse collaborate with?

Suggested answers are at the end of the chapter.

Etiology

There is a hereditary tendency for IBS. IBS is more common in women than men and in those who are young to middle-aged. Flare-ups can be caused by other illnesses, infections, or the menstrual cycle.

Signs and Symptoms

IBS is characterized by reports of gas, bloating, constipation, diarrhea, or alternating constipation and diarrhea. The patient also has feelings of abdominal bloating, with or without visible abdominal distention. Other symptoms include the rectal passage of mucus, a feeling of incomplete evacuation, abdominal pain, depression, anxiety, and palpitations.

Diagnostic Tests

Diagnosis of IBS is made based on history and physical examination along with stool examination, colonoscopy, and sigmoidoscopy to rule out other disorders. Avoiding milk products for a time may be advised to rule out lactose intolerance.

Therapeutic Measures

IBS is a chronic condition, but symptoms can generally be controlled through lifestyle, diet, stress management, and

NURSING CARE PLAN for the Patient With Inflammatory Bowel Disease

Nursing Diagnosis: Ineffective Coping related to inflammatory bowel disease

Expected Outcome: The patient will identify strategies that promote effective coping.

Evaluation of Outcome: Is the patient able to state strategies for effective coping?

Intervention

Identify patient’s knowledge of Crohn’s disease or ulcerative colitis. Rationale Many people have little knowledge of a disease unless they know someone who has it. Inaccurate information must be corrected.

Evaluation Does the patient verbalize information about ulcerative colitis and its effects on the body?

Intervention Encourage the patient to express feelings about the disease and how it may affect his or her life. Rationale Expressing feelings about the disease and its perceived effect enables the patient to identify and talk about concerns. Once identified, the health care team can then address these concerns. Evaluation Does the patient talk about feelings regarding the potential impact of the disease on his or her life?

Intervention Determine whether the patient would like to speak with a person of similar age from the Crohn’s and Colitis Foundation of America. Rationale Speaking with someone close in age with the same disease lets the patient know that he or she is not the only person having to cope with this disorder. It can also help him or her learn some strategies for effectively coping with the disease. Evaluation Does the patient show an interest in speaking with someone with the same disease?

Intervention Identify strategies for effective coping that are acceptable to the patient. Rationale Talking about concerns and possible solutions is a positive step. Coping strategies identified with the patient are more likely to be implemented. Evaluation Is the patient able to identify strategies for effective coping that he or she believes will work?
medication. See “Nutrition Notes” for diet. A high-fiber and high-bran diet (psyllium [Metamucil] or methylcellulose [Citruce]) may help to form softer, larger stools but may increase other symptoms in some people. Eating smaller, frequent meals can be helpful in reducing bowel contractions. Patients can keep a diary of foods eaten, stressors, and symptoms. This can help the HCPs identify flare-up triggers. Stress management, behavioral therapy (biofeedback, hypnosis, psychotherapy), and exercise are helpful in relaxing the bowel as well as contributing to overall health.

Various medications are used depending on the type of IBS. Antidepressants are given to block the brain’s perception of abdominal pain. For IBS with constipation, selective serotonin reuptake inhibitors (SSRIs) such as paroxetine HCl (Paxil) are given. Tricyclic antidepressants (such as amitriptyline HCl [Elavil]) are used for IBS with diarrhea because they tend to cause constipation. Antispasmodics such as hyoscyamine (Levbid) or dicyclomine (Bentyl) are used in IBS for diarrhea to relieve the painful colon spasms.

For women in whom treatment for IBS with constipation has not been successful, lubiprostone (Amitiza) may be used. It is a chloride channel activator that increases fluid secretion in the small intestine to help pass stool.

**Nursing Process for the Patient With IBS**

**Data Collection**

Height, weight, and data on the symptoms, including pain that the patient experiences, are collected. Timing of the symptoms, food and fluid intake, elimination patterns, effects on self-esteem, socialization, and personal and family roles are explored because IBS is a significant cause of missed work and school and also causes social withdrawal and embarrassment for people with it. Knowledge of the syndrome and its treatment are determined. Readiness for managing the syndrome is determined to plan care.

**Nutrition Notes**

**Low FODMAP Diet**

The Low FODMAP diet restricts certain carbohydrates that are known to cause symptoms in patients with IBS because of their poor absorption, osmotic activity, and rapid fermentation. FODMAP stands for Fermentable Oligosaccharides, Disaccharides, Monosaccharides, And Polyols. Up to 86% of patients with IBS have achieved relief of overall GI symptoms from the Low FODMAP Diet (Barrett, 2013).

The richest sources of the FODMAPs are:

- Fructooligosaccharides (fructans)—wheat, rye, onions, garlic, artichokes
- Galacto-oligosaccharides (GOSs)—legumes (soy, beans, chickpeas, lentils), cabbage, Brussels sprouts
- Lactose—milk, dairy products, beer, prepared soups and sauces
- Fructose—honey, apples, dates, mangoes, papaya, pears, prunes, watermelon, high fructose corn syrup
- Sorbitol—apples, pears, stone fruits, sugar-free mints/gums

• Mannitol—mushrooms, cauliflower, sugar-free mints/gums (Barrett & Gibson, 2012; Thomas, Nanda, & Shi, 2012).

Not all FODMAPs will trigger symptoms for all patients. Only those that are malabsorbed are likely to be clinically significant. Fructans and GOSs are always malabsorbed and fermented by intestinal bacteria, resulting in gas production and associated flatulence even in healthy people.

The remaining FODMAP carbohydrates will only induce symptoms in the patients with IBS that malabsorb them. Identification of susceptible patients can be achieved by breath tests after ingestion of lactose or fructose or by eliminating all FODMAP foods and relating their reintroduction to returning symptoms.

Individualizing the diet is important, particularly for vegetarians who may depend on legumes for protein intake, as it may show patients that they can cope with garlic as a minor ingredient, or wheat products occasionally which would expand the nutritional composition of their diet. The key issue is the total FODMAPs ingested at a meal, not the individual items. The low-FODMAP diet requires a registered dietitian’s expertise both to maximize compliance with instigating the complete list of FODMAP sources and to avoid an overly restrictive approach unnecessarily. The latter is of great import if the event the diet is successful and likely to be followed long term. Considerable evidence supports the efficacy of the low-FODMAP diet for IBS suggesting that this should be the first dietary strategy tried (Barrett & Gibson, 2012).

**Nursing Diagnoses, Planning, and Implementation**

**Constipation related to irregular motility of GI tract**

**EXPECTED OUTCOME** The patient will maintain passage of soft, formed stool every 1 to 3 days without straining.

• Assess normal pattern of defecation, diet and fluid intake, and medications to help identify factors contributing to constipation for planning care.
• Increase fluid intake, if not contraindicated, to 2 to 3 L per day to prevent hard stools.
• Teach patient about the benefits of increasing fiber and bran in the diet to promote soft, larger stools that are easier to pass.
• Give medication as ordered to control symptoms.
Diarrhea related to irregular motility of GI tract

**EXPECTED OUTCOME:** The patient will maintain formed, soft stool every 1 to 3 days.

- Obtain history including medications regarding diarrhea episodes to help identify cause.
- Monitor and record stool characteristics, amount, and frequency to plan care.
- Give antidiarrheal medications as ordered. Controlling diarrhea controls comfort and fluid balance.
- Limit caffeine intake because it stimulates intestinal motility.
- Keep skin clean, dry, and protected with a moisture barrier, such as petrolatum or medicated ointment, after each bowel movement to protect perianal skin from contact with liquid stools and their enzymes.

Readiness for Enhanced Self Health Management related to desire to manage symptoms of IBS

**EXPECTED OUTCOME:** The patient will state understanding and ability to carry out preventive measures to control symptoms before discharge.

- Explain IBS including symptoms, aggravating factors, and treatments to promote understanding, which will aid ability to follow therapeutic regimen.
- Encourage use of food diary documenting foods eaten and timing of symptom occurrence to identify food triggers for symptoms including lactose intolerance.
- Consult registered dietitian and share food diary to allow identification of food connection with symptoms and meal planning to prevent symptoms.
- If lactose intolerant, teach patient to avoid dairy products and substitute yogurt to reduce symptoms.

**Evaluation**

The plan has been effective if the patient has regular bowel function pattern, verbalizes understanding of self-care measures, and expresses satisfaction with the outcomes.

**ABDOMINAL HERNIAS**

Pathophysiology and Etiology

A hernia is an abnormal protrusion of an organ or structure through a weakness or tear in the wall of the cavity normally containing it, which in this case is the abdominal wall. Hernias are caused by a weakness in the abdominal wall along with increased intra-abdominal pressure, such as the pressure from coughing, straining, and heavy lifting. Obesity, pregnancy, and poor wound healing are also risk factors. The hernial sac is formed by the peritoneum protruding through the weakened muscle wall. Contents of the hernia can be small or large intestine or the omentum. Indirect hernias are caused by a defect of structural closure. Direct hernias are acquired and arise from a weakness in the abdominal wall, usually at old incisional sites.

Figure 34.4 illustrates the various types of hernias. Inguinal hernias are located in the groin where the spermatic cord in males or the round ligament in females emerges from the abdominal wall. This common hernia is an example of an indirect hernia and is usually seen in males.

Umbilical hernias are seen most often in obese women and in children. They are caused by a failure of the umbilical orifice to close. Ventral (incisional) hernias usually result from a weakness in the abdominal wall after abdominal surgery, especially in the obese patient, if a drainage system was used, the patient experienced poor wound healing, or the patient received inadequate nutrition.

**Prevention**

Congenital defects cannot be prevented. However, reducing strain on abdominal muscles is helpful. Those who do heavy lifting, tugging, or pushing should wear a support binder or avoid the lifting. A healthy lifestyle of maintaining normal weight, not smoking, and eating high-fiber foods is recommended.

**Signs and Symptoms**

Unless complications occur, few symptoms are associated with hernias. An abnormal bulging can be seen in the affected area of the abdomen, especially when straining or coughing. The patient may have some discomfort due to tension on tissues around the hernia. The herniation may disappear when the patient lies down. If the intestinal mass easily returns to the abdominal cavity or can be manually placed back in the abdominal cavity, it is called a reducible hernia. When adhesions or edema occur between the sac and its contents, the hernia becomes irreducible or incarcerated.
Complications

An incarcerated hernia may become strangulated if the blood and intestinal flow are completely cut off in the trapped loop of bowel. Strangulated hernias do not develop in adults very often. Incarceration leads to an intestinal obstruction and possibly gangrene and bowel perforation. Symptoms are pain at the site of the strangulation, nausea and vomiting, and colicky abdominal pain.

Therapeutic Measures

Hernias are diagnosed by physical examination. Treatment options include no treatment, observing the hernia, using short-term support devices, or surgery to cure the hernia. A supportive truss or brief applies pressure to keep the reduced hernia in place. Emergency surgery is needed for strangulation or the threat of bowel obstruction. Surgical repair is recommended for inguinal hernias. Surgical procedures are most often done laparoscopically and include hernioplasty (open or laparoscopically) or herniorrhaphy (open hernia repair). Herniorrhaphy involves making an incision in the abdominal wall, replacing the contents of the hernial sac, saving the weakened tissue, and closing the opening. Hernioplasty involves replacing the hernia into the abdomen and reinforcing the weakened muscle wall with wire, fascia, or mesh. Waterproof or a temporary colostomy may be necessary if the hernia is strangulated.

Nursing Care

The patient is instructed to avoid activities that increase intra-abdominal pressure, such as lifting heavy objects. The patient is taught to recognize signs of incarceration or strangulation and the importance of notifying the HCP immediately. If a support truss or brief has been ordered, the patient is taught to apply it before arising from bed each morning while the hernia is not protruding. Special attention should be paid to maintenance of skin integrity beneath the truss.

Postoperative Care

Care following inguinal hernia repair is generally similar to any abdominal postoperative care (see Chapter 12). Patients can perform deep breathing to keep lungs clear postoperatively but should avoid coughing. Coughing increases abdominal pressure and could affect the hernia repair. The male patient may experience swelling of the scrotum. Ice packs and elevation of the scrotum may be ordered to reduce the swelling. Because most patients are discharged the same day of surgery, they are taught to change the dressing and report difficulty urinating, bleeding, and signs and symptoms of infection, such as redness, incisional drainage, fever, or severe pain. The patient is also instructed to avoid lifting, driving, or sexual activities for 2 to 6 weeks as specified by the HCP. Most patients can return to nonstrenuous work within 2 weeks.

Absorption Disorders

The process of digestion reduces nutrients to a liquid form that can be absorbed through intestinal mucosa into the portal bloodstream. More than 8000 mL of liquid with nutrients and electrolytes is absorbed, mostly proximal to the ileocecal valve.

Pathophysiology and Etiology

Malabsorption occurs when the GI system is unable to absorb one or more of the major nutrients (carbohydrates, fats, or proteins). Some causes of malabsorption are ileal dysfunction, jejunal diverticula, parasitic disease, celiac disease, enzyme deficiency, and inflammatory bowel diseases such as Crohn’s disease and ulcerative colitis. The primary malabsorption disorders are celiac disease and lactose intolerance.

In celiac disease, a sensitivity to gluten is thought to cause malabsorption of protein. Gluten is a protein found in wheat, barley, and rye. Oats may become contaminated with gluten in the milling process of these other grains (“Nutrition Notes”).
A deficiency in lactase, an enzyme that breaks down lactose (milk sugar), causes lactose intolerance. When lactose is not digested, a high concentration of it occurs in the intestines, causing an osmotic retention of water in the colon and watery stools.

**Signs and Symptoms**

Weight loss, weakness, and general malaise resulting from malnutrition are associated with malabsorption disorders. Lactose intolerance causes abdominal cramping, excessive gas, and loose stools after eating milk products. Signs and symptoms of celiac disease can range from none to many in various body systems (see www.csaceliacs.org). Frequent loose, bulky, foul stools that are gray in color with an increased fat content may occur in celiac disease. Increased fat in the stool is named steatorrhea. Nutritional issues with celiac disease include iron-deficiency anemia secondary to poor iron absorption.

**Complications**

Vitamin K deficiency and resulting hypoprothrombinemia can increase the risk of bleeding. Calcium deficiency can be severe enough to cause bone pain and neuromuscular hyperirritability including tetany. Folic acid, vitamin B₁₂, and iron deficiencies can result in glossitis, stomatitis, anemia, and dry, rough skin.

**Diagnostic Tests**

See Table 34.7 for diagnostic studies used to identify malabsorption diseases.

**Therapeutic Measures**

**CELIAC DISEASE.** Patients with celiac disease are ordered a high-calorie, high-protein, gluten-free diet to relieve the symptoms, promote intestinal healing, and improve nutritional status. However, because gluten is used as a filler or binder in many products, even those labeled “wheat free,” diligence in identifying potentially offending foods is essential.

**LACTOSE INTOLERANCE.** Lactose intolerance is treated by removing foods from the diet that contain lactose, such as milk and milk products. Some fermented milk products, such as cheese and yogurt, may be lower in lactose and better tolerated. Lactaid is an over-the-counter lactase substitute that can be taken when milk products cannot be avoided. It can be added to milk in liquid form or taken as a tablet before eating foods containing lactose. Lactaid digests about 70% of the lactose in foods, making them more tolerable.

**Nursing Care**

Nursing care involves monitoring fluid and electrolyte balance, nutritional status, and skin integrity. Recording daily weight and intake and output helps determine if fluid loss is occurring. Intake of electrolyte-rich fluids is encouraged to replace losses. Antidiarrheal agents are given if ordered. Electrolyte levels, especially potassium, are monitored as ordered. The patient is instructed in dietary limitations. Nutritional supplements may be ordered if needed. Perianal skin is kept clean and dry, and barrier ointments are used as needed to protect the skin from excoriation.

**INTESTINAL OBSTRUCTION**

Intestinal obstructions occur when the flow of intestinal contents is blocked. The two types of intestinal obstruction are mechanical and nonmechanical, both of which can be either partial or complete.

Mechanical obstruction occurs when a blockage occurs within the intestine from conditions causing pressure on the intestinal walls such as adhesions, twisting of the bowel, or strangulated hernia. Nonmechanical obstruction occurs when peristalsis is impaired and the intestinal contents cannot be propelled through the bowel. Nonmechanical obstruction is seen following abdominal surgeries, trauma, mesenteric ischemia, or infection. The severity of the obstruction depends

| **TABLE 34.7 DIAGNOSTIC TESTS FOR DISORDERS OF MALABSORPTION** |
|---------------------------------|----------------------------------|
| **Diagnostic Test** | **Test Result and Associated Malabsorption Syndrome** |
| Hemoglobin and hematocrit | Decreased if anemia is present. |
| Mean corpuscular volume | Decreased values are found with malabsorption of vitamin B₁₂. |
| Upper GI series | Thickening of the intestinal mucosa, narrowed mucosa of the terminal ileum, or a change in fecal transit time are indicative of malabsorption syndrome. |
| D-xylene absorption test | Decreased excretion of xylose after 5 hours is indicative of malabsorption. |
| Sudan stain for fecal fat | Malabsorption can be distinguished from maldigestion if this test shows abnormally large numbers of fat droplets. |
| 72-hour stool collection for fat | Stool fat greater than 5 g per 24 hours after ingestion of 80 g of fat in 2 days implies a fat digestion disorder. |
| Biopsy | Shows flattened mucosa and loss of villi with celiac disease |

*Note: GI, gastrointestinal.*
on the area of bowel affected, the amount of occlusion within the lumen, and the amount of disturbance in the blood flow to the bowel (Table 34.8).

**Small-Bowel Obstruction**

**Pathophysiology**

When obstruction occurs in the small bowel, a collection of intestinal contents, gas, and fluid occurs proximal to the obstruction. The distention that results stimulates gastric secretion but decreases the absorption of fluids. As distention worsens, the intraluminal pressure causes a decrease in venous and arterial capillary pressure, resulting in edema, necrosis, and eventually perforation of the intestinal wall.

**Etiology**

Following abdominal surgery, loops of intestine may adhere to areas in the abdomen that are not healed. This may cause a kink in the bowel that occludes the intestinal flow. These adhesions, or bands of scar tissue, are the most common cause of small-bowel obstruction and are usually acquired from previous abdominal surgery or inflammation. Hernias and neoplasms are the next most common causes, followed by inflammatory bowel disease, foreign bodies, strictures, volvulus, and intussusception. A volvulus occurs when the bowel twists, occluding the lumen of the intestine. Intussusception occurs when peristalsis causes the intestine to telescope into itself (Fig. 34.5).

These conditions are mechanical obstructions. Paralytic, or adynamic, ileus is a nonmechanical obstruction that occurs when the intestinal peristalsis decreases or stops because of a vascular or neuromuscular pathological condition. Box 34-1 lists causes of nonmechanical obstructions.

**Signs and Symptoms**

The patient initially reports wavelike abdominal pain and vomiting. Initially, flatus and feces that are low in the bowel and blood and mucus may be passed, but this stops as the obstruction becomes worse. The symptoms progress as the obstruction worsens or becomes complete. As the obstruction becomes more extreme, peristaltic waves reverse, propelling the intestinal contents toward the mouth, eventually leading to fecal vomiting. Peristaltic waves may be visible in a thin person. Pain and abdominal distention are present. Pain that is sharp and sustained may indicate perforation. In mechanical obstructions, high-pitched, tinkling bowel sounds are heard proximal

to the obstruction and are absent distal to it. If the obstruction is nonmechanical, there is an absence of bowel sounds.

Loss of fluid and electrolytes leads to dehydration, with its associated symptoms of extreme thirst, droveness, aching, and general malaise. The lower in the GI tract the obstruction is, the greater the abdominal distention. An uncorrected obstruction can lead to shock and possibly death.

**Diagnostic Tests**

Dilated loops of bowel are evident in radiographic studies and CT scans. If strangulation or perforation occurs, leukocytosis is evident. Hemoglobin and hematocrit levels are elevated if the patient is dehydrated, and serum electrolyte levels are decreased.

**Therapeutic Measures**

In most cases, the patient is NPO and bowel decompression is present, enemas and manual disimpaction may be begun. Complete mechanical obstruction requires surgical intervention, such as removal of tumors, release of adhesions, or bowel resection with anastomosis.

**Large-Bowel Obstruction**

**Pathophysiology**

Obstruction in the large bowel is less common and not usually as dramatic as small-bowel obstruction. Dehydration occurs more slowly because of the colon’s ability to absorb fluid and distend well beyond its normal full capacity. If the blood supply to the colon is cut off, the patient’s life is in jeopardy because of bowel strangulation and necrosis.

**Etiology**

Most large-bowel obstructions occur in the sigmoid colon and are caused by carcinoma, inflammatory bowel disease, diverticulitis, or benign tumors. Impaction of stool may also cause obstruction.

**Signs and Symptoms**

Symptoms of large-bowel obstruction develop slowly and depend on the location of the obstruction. If the obstruction is in the rectum or sigmoid, the only symptom may be constipation. As the loops of bowel distend, the patient may report crampy lower abdominal pain and abdominal distention. Vomiting, if it occurs, is a late sign and may be fecal. High-pitched tinkling bowel sounds may be heard. A localized tender area and mass may be felt on palpation. Large-bowel obstructions, if not diagnosed and treated, can lead to gangrene, perforation, and peritonitis.

**Therapeutic Measures**

Radiological examination reveals a distended colon. If impaction is present, enemas and manual disimpaction may be effective. Other mechanical blockages may require surgical intervention.

Surgical resection of the obstructed colon may be necessary. A temporary colostomy may be indicated to allow the bowel to rest and heal. Sometimes an ileoanal anastomosis is done. A patient who is a poor surgical risk may have a colectomy (an opening from the cecum to the abdominal wall) to allow diversion of stool.

**Nursing Process for the Patient With a Bowel Obstruction**

**DATA COLLECTION.** Each quadrant of the abdomen is auscultated for bowel sounds to identify the location of the obstruction. The abdomen is palpated for distention, firmness, and tenderness. The amount and character of stool, if any, are documented. Pain is assessed using the institution’s pain scale and described according to location and character, such as crampy or wave-like. Vital signs are monitored for signs of infection or shock. Daily weight and intake and output are monitored. Serum electrolytes are also monitored for bowel sounds to identify the location of the obstruction.

**EXPECTED OUTCOME:** The patient will state pain is relieved or at an acceptable level within 30 minutes of report of pain.

- Assess pain level using rating scale to consistently communicate patient level.
- Give medications ordered for pain cautiously because they may mask symptoms of perforation and decrease intestinal motility.
- Position patient in semi-Fowler’s position to reduce tension on the abdomen.

**Risk for Deficient Fluid Volume related to vomiting**

**EXPECTED OUTCOME:** The patient will maintain vital signs and urine output within normal limits at all times.

- Accurately monitor intake and output and note trends to identify fluid deficit.
- Maintain fluid replacement as ordered to prevent dehydration.

**Risk for Electrolyte Imbalance related to suctioning**

**EXPECTED OUTCOME:** The patient will maintain vital signs and urine output within normal limits at all times.

- Monitor electrolyte values to identify imbalances.
- Monitor vital signs, and watch for signs of electrolyte imbalances such as weakness accompanied by low potassium levels to identify imbalances for prompt treatment.
- Give ice chips sparingly if ordered by the HCP. Melted ice increases electrolyte and hydrochloric acid removal when suctioned from the stomach, and electrolyte imbalance and metabolic alkalosis occur.

**Risk for Dysfunctional Gastrointestinal Motility**

**EXPECTED OUTCOME:** The patient will maintain passage of flatus and stool.

- Monitor GI function for presence of flatus and bowel movements to detect problems.
Hemorrhoids

Hemorrhoids are enlarged veins within the anal tissue. They are caused by an increase in pressure in the veins, often from increased intra-abdominal pressure. Internal hemorrhoids occur above the internal sphincter, and external hemorrhoids occur below the external sphincter. Most hemorrhoids are caused by straining during bowel movements. They are common during pregnancy. Prolonged sitting or standing, obesity, and chronic constipation also contribute to hemorrhoids. Portal hypertension related to liver disease may also be a factor.

Internal hemorrhoids are usually not painful unless the y prolapse. They may bleed during bowel movements. External hemorrhoids cause itching and pain when inflamed and filled with blood (thrombosed). Inflammation and edema occur with thrombosis, causing severe pain and possibly infarction of the skin and mucosa over the hemorrhoid.

Treatment is aimed at preventing constipation, avoiding straining during defecation, maintaining good personal hygiene, and making lifestyle changes to relieve any hemorrhoid symptoms and discomfort. Increased fluid intake and stool softeners can be used to reduce the need for straining. Daily sitz baths increase circulation to the area and aid in comfort and healing. Prolonged standing and sitting are avoided. Astringents, such as witch hazel, can be used for symptom relief. Anti-inflammatory medications may be tried, such as steroid creams or suppositories. Alternating ice and heat helps relieve edema and pain for thrombosed hemorrhoids. The blood clot will be removed by a HCP.

If surgery is required for internal hemorrhoids methods include rubber-band ligation using a rubber band around the hemorrhoid that cuts off the blood supply, causing the hemorrhoid to slough off into the stool; infrared coagulation that burns off the hemorrhoid; sclerotherapy that shrinks the hemorrhoid with a chemical solution; hemorrhoidectomy to surgically remove the hemorrhoid.

Patient education includes prevention and self-care. The patient should be instructed to consume a high-fiber diet and 2 to 3 L of fluid a day to promote regular bowel movements. The effects and side effects, proper dosage, and frequency of local or topical medications should be explained.

If the patient has surgery, analgesics are given as needed because the many nerve endings in the anal canal can cause severe pain. Comfort measures such as a side-lying position and fresh ice packs can be used to relieve pain. After the first postoperative day, sitz baths may be ordered. Unfortunately, a side effect of opioid analgesics is constipation, which needs to be avoided, especially in the immediate postoperative period. Because the first bowel movement can be painful and anxiety provoking, stool softeners are given and analgesics administered before the first bowel movement.

Anal Fissures

Anal fissures are cracks or ulcers in the lining of the anal canal. They are most commonly associated with constipation and stretching of the anus with passage of hard stool, although Crohn’s disease or other factors may also play a role. The patient may experience bright red bleeding. Pain may be so severe that the patient delays defecation, leading to further constipation and worsening symptoms. Treatment of anal fissures involves measures to ensure soft stools to allow fissures time to heal. Sitz baths may be used to promote circulation to the area to aid in healing. Anesthetic suppositories and nonopioid analgesics may be ordered for comfort. If conservative measures are not helpful, surgical excision of the fissure may be needed.

Anorectal Abscess

An anorectal abscess is a collection of pus in the rectal area. Common causative organisms include Escherichia coli, Proteus spp., staphylococci, or streptococci. Symptoms include pain, redness and swelling, fever, and sometimes drainage. Abscesses are treated with antibiotics and surgical incision and drainage of pus. The area may be left open to drain, with gauze packing placed to assist with drainage and healing.

Nursing Care

Nursing care includes dressing or packing changes as ordered. Sitz baths are used to keep the area clean and promote healing,
especially after bowel movements. The patient is instructed in the importance of keeping the area clean and dry. Other postoperative care is similar to care following hemorrhoidectomy.

### LOWER GASTROINTESTINAL BLEEDING

#### Etiology
Major causes of lower GI bleeding are diverticulitis, polyps (growths in the colon), anal fissures, hemorrhoids, inflammatory bowel disease, and cancer.

#### Signs and Symptoms
Bleeding from the GI tract is seen in the stool. When blood has been in the GI tract for more than 8 hours and has come in contact with hydrochloric acid, it causes melena, or black and tarry stools. The presence of melena indicates bleeding above or in the small bowel. Bleeding from the colon or rectum is usually bright red (hematochezia).

Significant blood loss causes hypotension, lightheadedness, nausea, and diaphoresis. The patient may be pale and have cool skin. The onset of tachycardia and worsening hypotension indicate hypovolemic shock and should be reported to the HCP immediately.

#### Diagnostic Tests
A thorough history is necessary to determine underlying disorders that may be causing the bleeding. Decreased hemoglobin and hematocrit levels result from blood loss. Blood urea nitrogen (BUN) may be elevated as a result of breakdown of proteins in the blood by the GI tract. Stool can be tested for occult blood if it is not evident on inspection. Digital examination, colonoscopy, or sigmoidoscopy may be done by the HCP.

#### Therapeutic Measures
Treatment involves correction of the cause of the bleeding: surgery to correct diverticulosis, to correct inflammatory bowel disease, or to resect cancer may be considered.

#### Nursing Care
Stools are checked for the presence and amount of blood. Vital signs are monitored for signs of shock. Decreasing blood pressure and rising heart rate are reported to the HCP immediately. The patient is prepared for diagnostic tests, and nursing care for the underlying disorder is provided.

### COLON CANCER

#### Pathophysiology and Etiology
Colorectal cancer is one of the most common types of internal cancer in the United States. It originates in the epithelial lining of the colon or rectum and can occur anywhere in the large intestine. People with a personal or family history of ulcerative colitis, colon cancer, or polyps of the rectum or large intestine are at higher risk for developing cancer. Colorectal cancer has also been linked with previous gallbladder removal and dietary carcinogens. A major causative factor is lack of fiber in the diet, which prolongs fecal transit time and in turn prolongs exposure to possible carcinogens. Also, bacterial flora is believed to be altered by excess fat, which converts steroids into compounds having carcinogenic properties. Lifestyle factors such as obesity, smoking, alcohol intake, and a large amount of red meat in the diet increase the risk of colon cancer.

#### Signs and Symptoms
Manifestations of colorectal cancer vary according to the type of tumor and the location. A change in bowel habits is the most common symptom (Table 34.9). Blood or mucus in stools may occur. Although all tumors cause varying degrees of obstruction, those in the descending colon and rectum generally do not cause anemia, weight loss, nausea, or vomiting.

#### Diagnostic Tests
Screening for colorectal cancer in those over age 50 is the best prevention, but screening rates could be higher. Screening guidelines can be found in Chapter 11 or on the American Cancer Society’s website at www.cancer.org.

Home screening for blood in the stool can be done with a home colon cancer test kit. Immunological tests look for small amounts of blood. If blood is found, a HCP should
be contacted for follow-up. Most colorectal cancers are identified by biopsy done at the time of endoscopy (proctosigmoidoscopy, sigmoidoscopy, or colonoscopy). A CT scan can perform a virtual colonoscopy to view the inside of the colon. The carcinoembryonic antigen blood test is used to assess response to treatment of GI cancer. Carcinoembryonic antigen is present when epithelial cells rapidly divide and provides an early warning that the cancer has returned.

**Therapeutic Measures**

Small, localized tumors may be excised and treated during endoscopy or laparoscopy. These procedures can also be used as palliative care for patients with advanced tumors who cannot tolerate major surgery. If a tumor is causing obstruction, a stent can be placed to keep the colon open for bowel function until surgery.

Surgery is performed either to resect larger tumors and anastomose the remaining bowel or to create a fecal diversion by forming an ostomy. A variety of surgical procedures can be done depending on the location and extent of the cancer (Table 34.10 and Fig. 34.6). Medical management can include radiation therapy, chemotherapy, and monoclonal antibody therapy. When used, along with surgery, increased survival rates have been demonstrated.

Monoclonal antibody therapy uses antibodies that are made in a laboratory and work like normal antibodies do. They can enhance immune system function, interfere with the cancer cell’s growth, or even carry treatment such as drugs.

</table>
or radiation to cancer cells. The antibody is designed to attach to cancer cells to flag them for the immune system so they can be destroyed. Bevacizumab (Avastin) blocks the making of new blood vessels to deprive cancer cells of nourishment. Cetuximab (Erbitux) blocks the cell’s growth signal to stop it from growing.

**Complications**

Complications include bleeding, complete obstruction of the colon, perforation, anastomosis leaking leading to peritonitis, and extension of the tumor to adjacent organs. Colorectal cancer can metastasize to the lymphatic system and liver.

If the patient has an anastomotic leak, the location of the leak determines the effects that are seen. The patient may need to be NPO for up to 4 weeks to rest the GI tract and prevent more leakage and also receive high-dose antibiotic therapy such as ciprofloxacin (Cipro) or metronidazole (Flagyl). Ongoing monitoring includes WBCs, sedimentation rate, and fever. The patient will likely go home with special home care needs. A peripherally inserted central catheter line is placed to continue the antibiotic therapy.

**Nursing Process for the Patient With Colorectal Cancer**

**Data Collection**

Risk factors for colorectal cancer are identified by asking questions about the patient’s personal and family history: Is there a history of inflammatory bowel disease? What were the patient’s dietary habits? What foods were usually eaten, and how much fluid was usually consumed? Prior to diagnosis, did the patient experience constipation or diarrhea? Has there been a change in bowel habits? Has mucus or blood been noted in the stools? What social habits does the patient have? Did the patient smoke, drink alcoholic beverages, exercise? Has there been a recent weight loss? If so, how much and over what period of time? Does the patient admit to unusual fatigue or insomnia? Stool should be checked for mucus or blood.

If the patient has surgery, postoperative assessment includes monitoring vital signs and the return of flatus and bowel movements. Lung sounds are monitored for response to coughing and deep breathing and early ambulation. Dressings are observed for drainage. Large amounts of drainage or
bleeding are reported. If a drain is inserted in the perineal wound, moderate amounts of serosanguineous (light pink) drainage are expected. If the patient has an ostomy, it is monitored (see ostomy section later in the chapter).

**Nursing Diagnoses, Planning, and Implementation**

**Acute Pain related to tissue compression from the tumor**  
**EXPECTED OUTCOME:** The patient will report pain relieved or at an acceptable level.

- Have patient identify pain using a rating scale to identify pain level consistently.
- Administer analgesics as prescribed postoperatively to relieve pain.

**Fear related to serious threat to well-being**  
**EXPECTED OUTCOME:** The patient will state fear is reduced after information is given related to patient's condition.

- Assist patient in identifying fears to develop plan for reducing fears.
- Set aside time to allow the patient who so desires to talk, cry, or ask questions about the diagnosis and planned surgery to help reduce fear.
- Answer questions accurately to provide a trusting relationship.

**Imbalanced Nutrition: Less Than Body Requirements related to nausea and anorexia**  
**EXPECTED OUTCOME:** The patient will maintain normal weight for height and age.

- Give antiemetics as ordered to relieve nausea.
- Identify foods patients like and provide them to stimulate appetite.
- Give parenteral nutrition as ordered to provide depleted vitamins, minerals, and nutrients if the patient has been anorexic for any length of time or has had a significant weight loss.
- Provide the patient with a high-protein, high-calorie diet, as ordered, that is low in residue to decrease excessive peristalsis and minimize cramping.

**Evaluation**

Expected outcomes are that the patient verbalizes control of pain and less fear and attains an optimum level of nutrition.

**OSTOMY AND CONTINENT OSTOMY MANAGEMENT**

An ostomy is a surgically created opening (traditional abdominal incision or laparoscopic) that diverts stool or urine to the outside of the body through an opening on the abdomen called a stoma. A stoma is the portion of bowel that is sutured onto the abdomen. A continent ostomy uses an internal reservoir to collect stool. The types of abdominal ostomies include ileostomy, colostomy, and urostomy. (Urinary ostomies are discussed in Chapter 37.) The stomas can be end, loop, or double barrel (see Fig. 34.6). How do you think a patient would feel when being told he or she needs an ostomy?

**Ileostomy**

An ileostomy is an end stoma formed by bringing the terminal ileum out to the abdominal wall following a total proctocolectomy. Two types of ileostomies can be formed: a conventional ileostomy and a continent ileostomy, such as a Kock pouch (sometimes called a Koch pouch) or Barnett's continent internal reservoir, which is a modification of a Kock pouch (Fig. 34.7). A conventional ileostomy has a small stoma in the right lower quadrant that requires a pouch at all times because of the continuous flow of liquid effluent.

Continent ileostomies are formed by taking a portion of the terminal ileum to construct an internal reservoir with a nipple valve. A stoma is created and the patient is taught to insert a catheter into the stoma three or four times a day to empty the reservoir. A continent ileostomy surgical procedure takes longer and requires additional instruction for the patient to be able to do self-care. It is important for the patient to empty the pouch routinely to prevent pouch rupture. Complications can occur, especially for the Kock pouch, such as valve slippage or leaking, pouch rupture, or pouchitis. Corrective surgery may be required.

**FIGURE 34.7** Surgical formation of continent ileostomy (Kock pouch). (A) Loop of terminal ileum. (B) Both limbs of ileum are brought together and sutured into a U shape. (C) Pouch created with nipple valve. (D) Pouch sutured to abdominal wall.
An ileoanal anastomosis connects the ileum to the anus and avoids the need for a stoma (Fig. 34.8). This is usually a two-step procedure. During the first surgery, the diseased bowel is removed. A reservoir (named by its shape: J [most common], S, W, or H pouch) is then formed from part of the ileum and connected to the anus. A temporary ileostomy is also formed to divert stool while the reservoir heals. After about 3 months, the temporary ileostomy is reversed and the patient can have bowel movements from the anus. Problems with perianal skin irritation resulting from frequent liquid stools may occur. An ileorectal anastomosis can also be performed, but this may not be a curative procedure for a patient with ulcerative colitis because the rectum may still be diseased.

Colostomy
A colostomy is named according to where in the bowel it is formed: it may be an ascending, transverse, descending, or sigmoid colostomy. The type of effluent is dependent on the location of the bowel used (Table 34.11).

End Stoma
An end stoma is formed when the proximal end of the bowel is brought to the outside abdominal wall. If an abdominoperineal (AP) resection is done, the rectum is removed, and the proximal sigmoid or descending colon is brought out as a stoma. Another procedure that may be done involves removing the segment of diseased or injured bowel and using the proximal portion to form the stoma. The remaining limb of bowel is sutured closed and left in the peritoneal cavity so that the rectum is intact. This is called a Hartmann’s pouch, or mucous fistula, and may be permanent or temporary depending on the diagnosis. Because the rectum is intact, the patient may feel the urge to defecate. This is normal because the colon continues to produce mucus. As the rectal stump fills with mucus, the sphincter is triggered and alerts the patient as if it were stool.

Loop Stoma
To create a loop stoma, a loop of bowel, usually the transverse colon, is pulled to the outside abdominal wall and a bridge is slipped under the loop to hold it in place. An incisional slit is made in the top of the exposed colon to allow stool to exit. The entire loop of bowel is not cut through.

Double-Barrel Stoma
With a double-barrel stoma, the bowel is completely dissected, and both ends of the colon are brought to the outside abdominal wall to form two separate stomas. The proximal stoma is the functioning stoma that expels stool. The distal stoma is called a mucous fistula because mucus produced by the bowel passes from it. A double-barrel stoma is often temporary, allowing the bowel to rest during healing after trauma or surgery.

Preoperative Care
A wound ostomy continence nurse (WOCN) should be consulted before surgery. The WOCN can help prepare the patient both emotionally and physically for the surgery. In addition, the WOCN has expertise in selecting the stoma site for the surgeon to ensure that it is easy to sit with it, care for

LEARNING TIP
As stool travels through the colon, water is absorbed and the stool becomes firmer. Therefore, an ileostomy produces the most liquid effluent, followed by an ascending colostomy. A descending or sigmoid colostomy produces the firmest stool. Those with an ileostomy are at increased risk for dehydration due to greater water loss.

FIGURE 34.8 Ileal J pouch-anal anastomosis. The two-loop ileal pouch is simple to construct, provides adequate storage capacity, and is evacuated spontaneously and fully.
it, and wear clothing over it. This involves observing the abdomen as the patient assumes different positions and noting how clothing is worn, such as where the belt rides. The site for the stoma can then be chosen so it is visible to the patient for self-care, avoids skin or fat folds, and is where clothing will not interfere with the appliance. Properly planned stoma placement can prevent discomfort when sitting, inability to perform self-care, and uncomfortable, leaking, or poorly fitting appliances postoperatively.

Routine preoperative instruction, including the importance of coughing and deep breathing, splinting, and early ambulation, is provided. Orders for cleansing of the bowel are performed to reduce the risk for infection following surgery. Unless the patient has chronic diarrhea related to IBD, an oral agent to cleanse the bowel is given. Oral and IV antibiotics are given as ordered.

**Nursing Process for the Patient With a New or Established Ostomy or Continent Ostomy**

**Data Collection**

For a patient with a new ostomy, in addition to routine postoperative assessment, a stoma should be inspected at least every 8 hours. The stoma should be pink to red, moist (similar to the inside of the mouth), and well attached to the surrounding skin (Fig. 34.9). A bluish stoma indicates inadequate blood supply; a black stoma indicates necrosis. Either complication should be reported to the HCP immediately for treatment, which may require that the patient return to surgery. Note edema of stoma. The stoma size gradually decreases over the first few weeks following surgery.

For both new and established ostomies, skin is assessed for irritation around the pouch and under the pouch each time it is changed. Ostomy discharge (effluent) is monitored and documented. Unexpected changes, such as liquid stool from a descending ostomy, are reported. For the patient with a continent ostomy pouch, assessing that regular emptying of the pouch is done is important to prevent rupture and leakage. The characteristics of the stool are noted for any type of continent ostomy so that problems can be reported.

**Nursing Diagnoses, Planning, and Implementation**

See the “Nursing Care Plan for the Patient With an Intestinal Ostomy” and Table 34.12.

**Deficient Knowledge related to ostomy**

**Expected Outcome:** Patient will demonstrate how to care for ostomy.

- Determine patient readiness and ability to learn and perform self-care. The patient experiencing pain, nausea, or vomiting is not likely to be ready to look at the ostomy or learn about ostomy care.
- Provide special instructions or a specific type of ostomy appliance for patients with special needs, such as blindness, deafness, language barrier, severe arthritis, or other physical conditions that limit ability to perform self-care, so they will be able to perform self-care.
- Include caregiver in teaching if the patient is not ready or able to learn. With short hospital stays, time for teaching is limited and must begin soon after surgery.
- Ensure referral to home care nurse is made to continue teaching in the patient’s home.
- Consult a WOCN or ostomy equipment supplier if needed to identify appliances suited to individual patient’s needs. Figure 34.10 shows types of appliances.
- Explain how to change appliance (Fig. 34.11) to promote self-care.
- Demonstrate how to apply appliance using moldable or traditional skin barrier to promote self-care. Moldable (able to change shape) skin barrier does not require measuring a pattern or cutting and does not leave a gap around the stoma.

**Figure 34.10** Appliances used for ostomies. The long sleeve at the lower left of the photograph is used to drain the bowel following irrigation. Reproduced with permission of Hollister Inc., Libertyville, IL.

- For the traditional skin barrier:
  - Measure stoma with a stoma-sizing guide initially with each appliance change because the stoma will shrink for up to 6 months.
  - Trace the stoma pattern on the cut to fit skin barrier and cut to fit, if using a nonmoldable barrier, to teach the patient proper size and shape because most stomas are not round.
  - Apply a moldable barrier ring or strips to the skin barrier as needed to fill in gaps or fit convex shapes to protect the skin and prevent leakage.
  - Fit the traditional skin barrier over the stoma on the skin with no gaps around the base of the stoma to prevent skin contact with stool.
  - Change appliance first thing in the morning every 3 days or every 10 to 14 days depending on the type of appliance to reduce skin shearing from frequent removal.
  - Change appliance immediately if leakage occurs to avoid peristomal skin irritation.
  - Use an open-ended or drainable pouch for all colostomies or ileostomies, especially during the first 8 weeks after surgery to facilitate emptying and comfort.
  - Explain to the patient who has a left-sided (descending or sigmoid) colostomy that the bowel can be regulated either by diet or regular irrigation of the stoma. After bowel regulation has been achieved, the patient may use a closed-end pouch or a stoma cap.
  - Explain daily care and hygiene:
    - Empty pouch when it is one-third to one-half full. The amount of effluent and the frequency of emptying depend on the location of the stoma in the bowel. If the pouch is allowed to get more than half full of stool, the weight of the effluent will pull on the pouch and weaken the seal of the skin barrier.

**Word Building**

*peristomal:* peri—surrounding + stoma—mouth or opening
• Empty pouch and then clean inside of the tail of the pouch before the self-seal or clamp is replaced to help control odor.

• Place deodorants in the pouch to control odor.

• Bathe or shower with the appliance in place but check seal and retape or change it if it is loosening. Water will not harm stoma or leak into stoma.

• Explain dietary considerations:
  • Identify foods that contribute to odor and gas. If foods that are known to cause odor or gas are eaten, the patient should know to empty the pouch of flatus more often and to be aware that more odor is probable.
  • Identify foods that contribute to and control diarrhea and what to do for constipation. A list of foods that may contribute to ileostomy blockage must be given to the ileostomy patient (Box 34-2 and “Nutrition Notes”).

Readiness for Enhanced Self Health Management related to difficulty carrying out self-care measures

EXPECTED OUTCOME Patient will demonstrate ability to perform self-care measures.

• Identify financial ability to obtain supplies. The cost and availability of ostomy supplies is problematic for

Nutrition Notes

Anticipating Dietary Management of Ostomies

Ostomy patients receive a soft diet initially, progressing to a general diet as the surgeon prescribes. Stringy, high-fiber foods are initially avoided until a definite tolerance has been demonstrated and then are best tried in small amounts, one at a time. Stringy, high-fiber foods include the following:

• Cabbage (including coleslaw, sauerkraut), corn, peas, spinach

• Coconut, dried fruit, pineapple, membranes on citrus fruits

• Popcorn, nuts, seeds, skins of fruits and vegetables.

Some patients avoid beans, cruciferous vegetables (broccoli, Brussels sprouts), eggs, fish, beer, and carbonated beverages because they produce excessive odor. Dietary restrictions are usually based on individual tolerance.

Certain foods may be therapeutic because they thicken the stool, including:

• Applesauce, banana

• Cheese

• Creamy peanut butter

• Pasta, white bread, white rice

Patients with ostomies should be encouraged to do the following:

• Eat at regular intervals.

• Chew food well to avoid blockage at the stoma site.

• Drink adequate amounts of fluid.

• Avoid foods that produce excessive gas, loose stools, offensive odors, and undesirable bulk.

• Avoid excessive weight gain.

• Explain colostomy irrigation if ordered for descending or sigmoid colostomies (more formed stool):
  • Explain that colostomy irrigation is done to regulate bowel movements at a regular time.

  • Show how to perform irrigation (similar to an enema), with special equipment used to instill fluid into the bowel via the stoma. Because a stoma does not have a sphincter, specially designed tubing with a cone at the end is used to irrigate the ostomy. The cone prevents the fluid that is being instilled from flowing back out of the stoma.
many patients. Most insurers, including Medicare, pay for ostomy supplies, although some limit the type of appliance and number allowed per month. Each state-funded Medicaid system is different. The type of appliance needed to eliminate leakage may not always be covered, requiring the patient either to pay the difference or wear what the insurance company will provide. If the patient has no insurance, costs can be high. Some patients find they have to choose whether to purchase ostomy appliances or prescriptions with their limited funds. Fortunately, the pouches in most two-piece systems can be washed out and reused to save money (see “Home Health Hints”).

Box 34-2 Foods That Can Cause Ileostomy Blockage

Vegetables: celery, Chinese vegetables, coleslaw, corn, green leafy (collards, lettuce, mustards, spinach), mushrooms, popcorn, potato skins
Fruits: apple skins, coconut, dried fruits (apricots, dates, figs, raisins), grapes, orange membranes, pineapple, seedy fruits (raspberries, strawberries)
Nuts and seeds (e.g., coconut, poppy seeds)
Meats with casings: bologna, frankfurters, salami, other sausages

Home Health Hints

- Patients with ostomies may be able to have some of their supplies covered by insurance. The home health nurse can work with the medical supply store to assist the patient in receiving the needed equipment. Most companies will deliver supplies to the patient’s home.
- Foods such as broccoli, cauliflower, Brussels sprouts, and cabbage can cause increased malodorous gas production. Encourage the patient with a colostomy to eat these in moderation. Offer alternative choices, such as green leafy vegetables, carrots, and cucumbers.
- If the patient requires a stool for occult blood test, deliver a collection device (hat) before you visit to assist with obtaining the specimen. Plan to deliver the specimen to the laboratory the day it is collected.
- Dietary instruction is important for home health patients with lower GI disorders. Give instructions both verbally and in writing. Written format allows the patient to have the information available for review and to assist with creating a shopping list.

Sexual Dysfunction related to body image change or erectile dysfunction

**Expected Outcome:** Patient will discuss satisfying acceptable sexual practices for self and partner.

- Identify if male patient who had an AP resection is experiencing erectile dysfunction. This impotence may be transient, depending on the severity of nerve damage or edema associated with the surgery.
- Ensure consultation with urologist is made to treat erectile dysfunction if present.
- Encourage patients to discuss any concerns regarding sexuality with his or her sexual partner. This may help them work through any fears or embarrassment.
- Explain that attractive pouch covers can be purchased and worn to help disguise the pouch and its contents.
- Encourage personal hygiene and emptying ostomy pouch before sexual encounters to decrease odors and enhance experience.
- Refer to sex counselor who can suggest alternative sexual positions to increase satisfaction for partners.

Risk for Injury related to skin and stomal complications

**Expected Outcome:** The patient will remain free from injury with intact skin, red, moist stoma, and functioning ostomy.

- Identify allergies to prevent complications because allergic dermatitis from sensitivity to the adhesive may develop.
- Consult WOCN for complications associated with care of the ostomy. A WOCN has had specialized instruction in caring for the stoma and peristomal skin and has a wealth of information to offer.
- Use a protective skin paste to prevent skin breakdown from leakage.
- Apply a stoma powder to absorb moisture from broken skin around the stoma to allow the skin to heal.
- Remove tape and adhesive only when necessary to prevent skin shearing from frequent removal.
- Leave pouches on for several days unless leakage occurs to prevent skin shearing from frequent removal.
- Monitor for peristomal hernia to detect hernias that may develop around the stoma as a result of weakened abdominal muscles and cause leakage by the change in body contours associated with the hernia.
- Use a more flexible ostomy appliance if peristomal hernia is present to fit body contours better.
- Monitor for and report stomal prolapse, especially in older adults. Weakened abdominal muscles contribute to the falling down (or out) of the intestinal mucosa, which can make pouching difficult.
- Monitor stoma color and immediately report dusky or blue color, which occurs when there is circulatory compromise. This may arise as a result of vascular collapse, blockage in the mesentery of the intestines, or edema in the intestine from obstruction proximal to the stoma. Usually, necrotic tissue occurs only at the very end of the stoma and will eventually slough off, revealing viable mucosa.
• Explain signs and symptoms of an ileostomy blockage: absent stool, abdominal cramping, edematous stoma, and stoma color that is pale or dusky to detect it for treatment.
• Have patient consider what was eaten in the past 24 hours if blockage occurs because certain foods are considered to cause stomal blockage (see Box 34-2).
• Have the patient get into a tub of warm water (not too hot or cold), get into a knee-to-chest position, and sip on warm liquid, such as coffee, tea, bouillon, broth, or hot chocolate for an ileostomy blockage. If the blockage is partial, relief will occur fairly soon after these measures are taken.
• Explain to patient that if no relief is obtained, medical treatment should be sought. For a complete blockage, an ileostomy lavage must be performed by a HCP or WOCN.

**Evaluation**
The plan of care has been effective if the patient is able to accept the change in body image, competently care for the ostomy (or caregiver will), carry out self-care, is satisfied with sexual practices, and describes self-care measures to prevent or treat complications.

**Rehabilitative Needs**
Ensuring that the patient is becoming comfortable with self-care, is able to perform the ostomy appliance change, and is able to return to work or civic activities as before are the goals of care. The patient can generally perform any activity he or she was able to do before the ostomy including swimming. Several support resources are available (see DavisPlus).

---

**NURSING CARE PLAN for the Patient With an Intestinal Ostomy**

**Nursing Diagnosis:** Disturbed Body Image related to new ostomy

**Expected Outcome:** The patient will verbalize acceptance of intestinal ostomy before discharge.

**Evaluation of Outcome:** Is the patient able to verbalize acceptance of the ostomy?

**Intervention** Identify knowledge of self-care of ostomies. **Rationale** Many people have misconceptions regarding ostomies. Identification of misconceptions and “hearsay” knowledge is important to clarify or correct. **Evaluation** Does the patient verbalize appropriate knowledge of ostomy care?

**Intervention** Encourage patient to verbalize feelings about the stoma. **Rationale** Allowing the patient to express his or her feelings provides opportunity to identify and verbalize concerns, which then can be addressed by HCPs. **Evaluation** Does the patient discuss his or her feelings regarding the stoma with the nurse or significant other?

**Intervention** Explain the normal characteristics of the stoma before the patient’s first look. **Rationale** Helping the patient understand what to expect will help relieve anxiety. Being available to answer questions immediately also relieves anxiety. **Evaluation** Does the patient look at the stoma without hesitation?

**Intervention** Demonstrate ostomy appliance change and daily care and encourage patient participation. **Rationale** When the patient observes and participates in self-care, his or her self-concept improves. **Evaluation** Is the patient participating in self-care? Has the patient performed return demonstration of appliance change and emptying of pouch?

---

**SUGGESTED ANSWERS TO CRITICAL THINKING**

**Mrs. Burns**
You need to assess the situation before intervening. First, ask Mrs. Burns or her caregivers if she had a bowel movement that was inadvertently not charted. Next, ask Mrs. Burns if she feels constipated or if she has abdominal discomfort. Assess Mrs. Burns’ abdomen for distention and presence or absence of bowel sounds. A digital examination may be necessary to determine if a fecal impaction is present. If simple constipation appears to be the problem, the medical record should be checked for as-needed laxative or enema orders. Once Mrs. Burns has had a bowel movement, laxatives should be discontinued and preventive measures such as regular fluids, fiber, and exercise should be instituted.

Continued
## Judy Morrow

   - Characteristics of bowel elimination: frequency, characteristic of stool, amount, color, consistency.
   - Nutritional status: Weight loss, appetite, daily food intake, food likes/dislikes, irritating foods, fluid intake.
   - Anxiety and coping skills: Support systems, usual coping methods.

2. **Acute Pain** related to increased peristalsis and cramping
   - **Diarrhea** related to inflammatory process
   - **Risk for Deficient Fluid Volume** related to diarrhea and insufficient fluid intake
   - **Anxiety** related to symptoms and frequency of stools and treatment
   - **Impaired Skin Integrity** related to frequent loose stools
   - **Imbalanced Nutrition, Less Than Body Requirements** related to malabsorption
   - **Ineffective Coping** related to frequency of stools.

3. Further assess how Judy perceives that Crohn’s disease will affect her lifestyle. What does she know about Crohn’s disease? What is she concerned about? How has Crohn’s disease affected her ability to sleep, what she eats, her participation in sports, and her relationships with other people?

   Convey a caring manner to Judy by being accepting of her, listening actively to her concerns, and helping her to find acceptable ways of resolving them. Provide her with information that she needs about Crohn’s disease. Arrange to have a well-adapted person of approximately the same age from the Crohn’s and Colitis Foundation of America meet with her to share coping strategies with her.

4. Increased frequency of stools leading to fluid volume deficit and possibly shock symptoms; bleeding leading to anemia and hypovolemia and possibly shock symptoms.

5. HCP, dietician, psychologist, registered nurse.

## Mrs. Loos

1. The first consideration is to be aware of whether the patient is at risk for a small-bowel obstruction. After abdominal surgery, loops of intestine may adhere to areas in the abdomen that are not healed, causing a kink in the bowel that obstructs the intestinal flow.

   - Yes, due to her history of abdominal surgery she is at risk of adhesion development that can cause obstruction. If assessment findings confirm this possibility, the HCP should be contacted. Because of the nausea and the potential obstruction, withhold food and oral fluids until the HCP can be contacted.

   - Begin by asking the WHAT’S UP? questions, including exactly where the pain is occurring, how it feels, if there is anything that aggravates or alleviates the pain, when it started, how bad it is on a scale of 0 to 10, whether there are associated symptoms, and if Mrs. Loos has some insight regarding the cause of her problem. Then, in this order, inspect, auscultate, and palpate (doing the exam in this order prevents palpation from changing other assessment findings). Inspect her abdomen to note distention. Listen for bowel sounds for 5 minutes in each quadrant. Lightly palpate her abdomen noting tenderness or rigidity. Ask when her last bowel movement was.

   - Bowel sounds normal in all quadrants, abdomen flat, soft with no tenderness, flatus present.

   - Abnormal bowel sounds; either absent for a nonmechanical obstruction or for a mechanical obstruction, high-pitched, tinkling bowel sounds proximal to the obstruction and absent distal to it; pain; abdominal distention.

   - Findings should be discussed with the registered nurse or HCP. New orders such as an NG tube, NPO status, and pain management should be anticipated.

   - If improving, symptoms will be resolving: no nausea, abdomen soft, bowel sounds present in all quadrants, flatus present, and bowel movements normal. If condition is worsening or complications are developing, symptoms will not improve, and fecal vomiting and shock may occur.
Chapter 34  Nursing Care of Patients With Lower Gastrointestinal Disorders 777

REVIEW QUESTIONS

1. The nurse is collecting data on a patient admitted with a history of severe diarrhea. Findings include cool, pale skin, red tongue with furrows, blood pressure 102/74 mm Hg, pulse 106 beats per minute, respirations 20 per minute, temperature 99.9°F (37.7°C). Which action should the nurse take now?
   1. Report findings to registered nurse.
   2. Give acetaminophen (Tylenol) as ordered.
   3. Obtain bedside commode.
   4. Apply warm blankets.

2. The nurse is reinforcing patient teaching about laxative use. The nurse would evaluate the patient as understanding the teaching if the patient stated which of the following?
   1. “Laxatives may be used as needed.”
   2. “Regular laxative use can be harmful.”
   3. “Daily use of laxatives prevents constipation.”
   4. “Laxative use has no complications.”

3. The nurse is caring for a patient after an appendectomy. Which of the following interventions should the nurse include in the patient’s plan of care to prevent respiratory complications? Select all that apply.
   1. Pain control
   2. Early ambulation
   3. Bedrest
   4. Coughing, deep breathing
   5. Incentive spirometer

4. The nurse is reinforcing patient teaching. Which of the following foods would the nurse reinforce that the patient with ulcerative colitis is to avoid?
   1. Fresh fruits
   2. White bread
   3. Sweet dessert
   4. Meat

5. The nurse participated in a patient’s teaching session for care to prevent respiratory complications after a hernia repair. Which statement by the patient would indicate to the nurse that the patient understood the teaching?
   1. “I will cough every hour while awake.”
   2. “I will deep breathe four times daily.”
   3. “I will cough and deep breathe every hour.”
   4. “I will deep breathe every hour while awake.”

6. The nurse would evaluate the patient as understanding diet teaching for celiac disease if the patient selected which of the following foods to eat?
   1. Fresh fruit and oatmeal with milk
   2. Tomato juice and waffles
   3. Hard-boiled egg, bacon, and blueberries
   4. Banana, cream of wheat cereal, and coffee

7. The nurse is caring for a patient with a small-bowel obstruction who is NPO with an orogastric tube on low intermittent suction. Which of the following ongoing data would be a priority for the nurse to monitor and collect? Select all that apply.
   1. Intake and output
   2. Pain level
   3. Bowel sounds
   4. Pulse rate
   5. Edema

8. The nurse is caring for a patient who has a sudden onset of diarrhea with black tarry stools. Which action should the nurse take?
   1. Obtain vital signs
   2. Monitor output
   3. Ask about a history of food allergies
   4. Place the patient on NPO status

9. Which of these patient’s dietary habits does the nurse understand may increase the risk for development of colon cancer?
   1. High-fat, low-fiber intake
   2. High intake of milk and milk products
   3. Low-meat and protein intake
   4. Low-fat, high-carbohydrate intake

10. The nurse is caring for a 1-day postoperative patient who has a new end colostomy that is a dusky color. Which action is the priority for the nurse to take?
    1. Inform the HCP now.
    2. Monitor the stoma color in 4 hours.
    3. Check the stoma drainage in 1 hour.
    4. Place a new ostomy appliance over the stoma.

11. A patient with Crohn’s disease is to receive sulfasalazine (Azulfidine), 500 mg oral suspension four times daily. The oral suspension is available as 250 mg/5 mL. How many milliliters should the nurse give for the 0800 dose?
    1. 5 mL
    2. 10 mL
    3. 20 mL
    4. 50 mL

Answers can be found in Appendix C.

Nursing Care of Patients With Liver, Pancreatic, and Gallbladder Disorders

LAZETTE V. NOWICKI

LEARNING OUTCOMES

1. Explain the causes, risk factors, and pathophysiology of the various types of liver disease.
2. Describe therapeutic measures used for patients with liver disease.
3. Plan nursing care for the patient experiencing a liver disorder.
4. Explain the causes, risk factors, and pathophysiology of the various pancreatic disorders.
5. Describe therapeutic measures used for patients with pancreatic disorders.
7. Explain the causes, risk factors, and pathophysiology of gallbladder disorders.
8. Describe therapeutic measures used for patients with gallbladder disorders.

Hepatitis is an inflammation of the liver resulting from viral or bacterial infection, drugs, alcohol, or chemicals toxic to the liver, and metabolic or vascular disorders. Symptoms of hepatitis range from no symptoms to life-threatening symptoms due to death of liver tissue. Many people who are infected with hepatitis C, especially baby boomers (people born 1945–1965), are not aware of it and can live for 20 years without symptoms. Those infected can develop chronic infection, chronic liver disease, cirrhosis, or liver cancer. Risk factors for becoming infected with hepatitis C include sharing needles or other equipment to inject drugs. Also, health care providers (HCPs) who are exposed to the virus can become infected in the health care setting. Before 1992, when widespread screening of the blood supply began in the United States, hepatitis C was also commonly spread through blood transfusions and organ transplants. It is recommended by the Centers for Disease Control and Prevention (CDC; www.cdc.gov) that all baby boomers be tested for hepatitis C. Viral hepatitis is quite common and discussed below.

**Pathophysiology and Etiology**

**Viral hepatitis is usually caused by one of five viruses:**

- Hepatitis A virus (HAV)
- Hepatitis B virus (HBV)
- Hepatitis C virus (HCV)
- Hepatitis D virus (HDV)
- Hepatitis E virus (HEV)

The viral agents vary by mode of transmission, incubation period, symptoms, diagnostic tests, and preventive vaccines (Table 35.1). The infecting organism causes inflammation of the liver, with resulting damage to liver cells and loss of liver function. If damage involves the bile canaliculi (thin tubes that collect secreted bile), obstructive jaundice will occur. If complications do not occur, cells regenerate and normal liver function eventually resumes.

There are an estimated 72,000 new hepatitis A, B, and C infections in the United States each year (CDC, 2013). The incidence of all types of viral hepatitis is at a historic low. HAV is overall the most common cause of hepatitis and has a low mortality rate. However, HBV is more common among some groups, including health care workers and intravenous (IV) drug users.

**Prevention**

The hepatitis viruses are very resistant to a wide range of antiinfective measures, such as drying, heat, ultraviolet light exposure, freezing, and bleach and other disinfectants. At least 30 minutes in boiling water is required to destroy them. The best methods for preventing the transmission of the hepatitis viruses are careful attention to cleanliness and the use of vaccines to HAV and HBV or the use of immunoglobulin (Ig) after exposure. Ig can be given up to 2 weeks after exposure to HAV; up to 1 week with a second dose of Ig in 1 month after HBV exposure. Infection control precautions used should reflect the usual mode of transmission of the particular hepatitis virus.

Ig provides temporary, passive, nonspecific immunity to hepatitis. A vaccine for HAV and HBV is available that provides permanent, active immunity. Health care workers are strongly encouraged (and often required by employers as a condition of employment) to be vaccinated for HBV. Permanent, active immunity is acquired from the body’s own antibodies in response to an actual viral infection. The active immunity is to the specific virus to which the body has developed antibodies.

Public health measures such as health education programs, licensing and supervision of public facilities, screening of blood donors, and screening of food handlers are general measures to prevent the transmission of hepatitis viruses.

**BE SAFE!**

In the United States, 27 (93%) of the 29 HBV outbreaks involving adults in long-term-care facilities reported to the CDC since 1996 have been among residents with diabetes receiving assistance in blood glucose monitoring, and in recent years, the majority of these outbreaks have occurred in assisted living facilities (CDC, Morbidity and Mortality Weekly Report [MMWR], May 18, 2012).

Breaks in infection control procedures were identified in an assisted living facility in which eight residents who contracted acute hepatitis B infection (six died) were assisted in blood glucose monitoring by staff whereas none of the residents performing their own glucose monitoring were infected (Centers for Disease Control, MMWR, February 18, 2011).

Follow infection control procedures whenever performing invasive procedures to keep your patients protected and safe.

**Signs and Symptoms**

Hepatitis usually shows a typical pattern of loss of liver function, which generally occurs in three stages:

1. The prodromal (preicteric [prejaundice]) stage occurs about 2 weeks after exposure to the hepatitis virus and lasts about 1 week. The patient reports flulike symptoms of malaise, headache, anorexia, low-grade fever, possibly dull right upper quadrant (RUQ) pain, nausea, vomiting, and diarrhea or constipation.

</table>

Note. Anti = antibody; ALT = alanine aminotransferase; EIA = enzyme-linked immunosorbent assay (ELISA-2); Ig = immunoglobulin; IV = intravenous; RUQ = right upper quadrant; RIBA = recombinant immunoblot assay.
2. With the appearance of jaundice (see Chapter 32),
the icteric stage begins (Fig. 35.1). It occurs about
5 to 10 days after the prodromal stage and lasts 2 to
6 weeks. The patient continues to have prodromal
symptoms. Dark urine can be present due to
increased bilirubin. The liver is usually enlarged
and tender on examination.
3. The convalescent stage (posticteric) begins when
the patient starts feeling better. It can last from
2 to 6 weeks. Recovery varies and depends on
the type of hepatitis. Full recovery is measured
by the return to normal of all liver function tests
and may take as long as 1 year. The effects of
hepatitis can be considered reversible if the
patient adheres to a medical regimen of adequate
rest, proper nutrition, and abstinence from
alcohol and other liver-toxic agents for at least
1 year after liver function laboratory values
return to normal.

Complications
Hepatitis may lead to fulminant (sudden, severe), acute or
chronic liver failure. Chronic infection can develop in those
with HBV or HCV. Some people are asymptomatic carriers
of HBV or HCV and never have an active illness. However,
they can infect others and have a greater risk of developing
cancer of the liver.

Diagnostic Tests
Serum liver enzymes are elevated (Table 35.2). Serum
bilirubin may be elevated. In patients with severe hepatitis,
prothrombin time may be prolonged. Serological tests can
determine the specific virus causing the hepatitis via viral
antigens and also identify the presence of antibodies to the
virus (see Table 35.1). Abdominal x-ray examination may
show an enlarged liver. Liver biopsy is done to assess liver
damage and healing.

### TABLE 35.2 LABORATORY TESTS FOR LIVER FUNCTION IN HEPATITIS
AND CIRRHOSIS

<table>
<thead>
<tr>

<th>Normal Value</th>
<th>Significance of Abnormal Findings</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Indicate Liver Damage</strong></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
| Alanine aminotransferase (ALT)| **Male:** 10–40 units/L  
Female: 7–35 units/L | Most specific enzyme for liver damage. Released with death of liver cells. |
| Aspartate aminotransferase (AST)| **Male:** 15–40 units/L  
Female: 13–55 units/L | Enzyme found in liver and heart; released and elevates  
10 times or greater than normal with death of liver cells. |
| Alkaline phosphatase (ALP)    | **Male:** 35–142 units/L  
Female: 25–125 units/L | Enzyme found in liver and bone; released and elevates  
greatly with severe liver damage. |
| **Measures Functioning of Liver** |                               |                                                                       |
| Albumin                       | 3.4–4.8 g/dL                  | Decreased because of impaired protein synthesis; edema  
and ascites may result.                                              |
| Ammonia                       | 15–45 mcg/dL                  | Increased because liver cannot metabolize protein end  
product; contributes to hepatic encephalopathy.                     |
| Bilirubin                     | 0.3–1.2 mg/dL                 | Increased because the liver is unable to use it to produce bile.       |
| Prothrombin time (PT)         | 11–13.5 seconds               | Prolonged. Liver can no longer make prothrombin; patient bleeds easily. |

**Therapeutic Measures**

Treatment goals are to identify the cause of hepatitis, monitor liver status, and provide symptom relief and supportive care. To promote healing with acute infection, limited activity with bathroom privileges and adequate nutrition and fluids are ordered. As the patient improves, activity may be increased as tolerated. Patients should avoid using alcohol or drugs that are known to be toxic to the liver (Box 35-1).

To manage chronic hepatitis B infection, the anti virals adefovir (Hepsera) or lamivudine (Epivir) may be used. Interferon therapy (peginterferon alpha-2b [Peg-Intron] or interferon alpha-2a [Pegasys]) along with an anti viral medication (oral ribavirin [Rebetol]) is considered to prevent chronic hepatitis C infection. A new drug, sofosbuvir (Sovaldi; a nucleotide analog inhibitor) was approved for treating adults with chronic hepatitis C infection. For more information, visit the websites of the Hepatitis Foundation International (www.hepfi.org), the CDC (www.cdc.gov), or the American Liver Foundation (www.liverfoundation.org).

**Nursing Process for the Patient With Hepatitis**

**DATA COLLECTION.** Identify subjective data such as malaise, fatigue, pruritus (itching), nausea, anorexia, and RUQ abdominal pain. Objective data, such as baseline weight, vomiting, pale stools, dark-colored (tea-colored) urine, and jaundice, are recorded. The patient’s vital signs are taken, and a low-grade fever or any abnormal bruising or bleeding is reported immediately. Ask the patient about his or her knowledge of disease process and how to prevent spread of the disease.

**Box 35-1 Common Causes of Hepatic Inflammation**

**Medications**
- Acetaminophen (Tylenol)
- Acetylsalicylic acid (aspirin)
- Allopurinol (Zyloprim)
- Captopril (Capoten)
- Carbamazepine (Tegretol)
- Diazepam (Valium)
- Erythromycin estolate (Ilosone)
- Estrogen
- Halothane (Fluothane)
- Isoniazid (INH)
- Metotrexate (Treall)
- Methyldopa (Aldomet)
- Oral contraceptives
- Phenobarbital (Luminal)
- Phenytoin (Dilantin)
- Sulfinamides
- Tetracycline (Sumycin)

**Metabolic Disorders**
- Alpha-1 antitrypsin deficiency
- Hemochromatosis (iron buildup)
- Wilson’s disease (copper buildup)

**Toxins**
- Ethyl alcohol
- Carbon tetrachloride
- Choleystographic dyes
- Kava-containing products (herb)
- Poisonous wild mushrooms
- Trichloroethylene
- Toluen

**Vascular Disorders**
- Budd-Chiari syndrome (hepatic vein occlusion)
- Heart failure
- Shock

**Viruses**
- Cytomegalovirus
- Epstein-Barr
- Hepatitis A, B, C, D, E
- Herpes
- Yellow fever

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

**EXPECTED OUTCOME** The patient will state that pain level is acceptable.

- Monitor pain level on 10-point scale, including WHAT’S UP? questions to determine treatment needs.
• For continuous pain, provide analgesics around the
clock and as needed (prn) analgesics for intermittent
breakthrough pain to provide comprehensive pain relief.
• Give analgesics as ordered, recognizing that lower doses
might be needed with liver dysfunction, to control pain.
• Avoid use of acetaminophen (Tylenol) and combination
drugs containing acetaminophen due to risk of liver
toxicity.
• Encourage nondrug pain relief, such as distraction,
imagery, and relaxation to supplement and possibly
decrease need for analgesics.

Imbalanced Nutrition, Less Than Body Requirements related
to anorexia, nausea, or vomiting

**EXPECTED OUTCOME:** The patient’s weight will be stable and
appropriate for height.

• Obtain baseline nutritional status with a nutritional screening
tool to identify malnutrition and plan nutritional needs.
• Monitor weight and nutritional intake recording percentage
of food eaten to determine ongoing treatment needs.
• Make dietary referral to develop nutritional plan.
• Administer antiemetic drugs as ordered to reduce nausea
and increase appetite.
• Provide frequent, smaller meals because these may be
better tolerated than larger meals.
• Place the patient in an upright or sitting position for meals
to decrease abdominal discomfort.
• Serve meals in a quiet environment without unpleasant
noise or odors to increase intake by making eating as
pleasant as possible.
• Teach patient to avoid alcohol and vitamin supplements
unless specifically prescribed by the physician to prevent
further damage to liver because alcohol and some vita-
mins are metabolized by the liver.

Risk for Impaired Liver Function related to viral infection

• Monitor liver function tests to detect liver infections.
• Monitor for signs of liver dysfunction: ascites, mental
changes (check ammonia levels), bleeding (check
coagulation studies) to report for implementation of
supportive interventions.
• Review medications for hepatotoxicity to protect liver
function.
• Calculate acetaminophen daily dosage so daily limit of
3000 mg or less is not exceeded if applicable to protect
liver function.
• Administer medication as ordered carefully in consideration
of liver effects to preserve liver function.
• Refer to alcohol cessation program if applicable to pre-
serve liver function.

Risk for Impaired Skin Integrity related to itching secondary
to bilirubin pigment deposits in skin

**EXPECTED OUTCOME:** The patient’s skin will remain intact
and free from secondary infection.

• Administer antihistamines as ordered to decrease
itching.

• Encourage the patient not to scratch but to press firmly on
the itchy area. Scratching can damage skin and increase
risk for infection.
• Encourage the patient to keep fingernails trimmed short so
that vigorous scratching does not tear the skin.
• Maintain room temperature at a comfortable level to
decrease perspiration, which may increase itching.

Risk for Ineffective Self Health Management related to lack of
knowledge of hepatitis and its transmission and treatment

**EXPECTED OUTCOME:** The patient will state how to self-
manage the treatment regimen for viral hepatitis and how
to prevent spread of the disease.

• Determine patient’s knowledge of hepatitis to plan

  teaching.
• Teach patient how hepatitis affects the body and the
importance of adequate rest and proper nutrition to
promote recovery.
• Teach the importance of avoiding alcohol and other
liver-toxic drugs, to prevent further damage to liver.
• Teach patient how to prevent spreading virus to others:
hand washing after toileting, using soap and hot water
to clean eating utensils, cookware, and food preparation
surfaces, practicing safer sex (abstinence, condoms,
monogamy), and not sharing needles because hepatitis
is contagious. (See “Home Health Hints.”)

---

**Home Health Hints**

• For patients with hepatitis, home health nurses
are concerned with proper treatment and
patient education to prevent transmission in
the community.
• If possible, the patient with hepatitis should have a
separate bedroom and bathroom. The person
cleaning the bathroom should wear disposable
gloves or rubber gloves and then clean the gloves
with a 10% bleach solution. The family is advised
to use liquid soap instead of bar soap.
• Contaminated linens used by a patient with hepato-
itis should be washed separately from household
laundry and in hot water. One cup of bleach
should be added with the detergent to each load.
Rubber gloves should be worn to wash the
patient’s laundry.
• A patient with abdominal ascites needs a hospital
bed at home so the patient can be positioned to
aid in breathing. A physician’s order must be ob-
tained for insurance coverage.
• Measure abdominal girth of the patient with ascites
at each visit and record in the nurse’s notes. The
patient should weigh on the same scale, first thing
in the morning, and record the weight so the nurse
can document the findings.
EVALUATION. Management of the patient with hepatitis has been successful if the patient reports pain is satisfactorily relieved; body weight is maintained within 2 pounds of pre-illness weight; skin has no breaks, cuts, or tears, or secondary infections; patient can define disease; and patient follows transmission precautions and treatment.

Acute Liver Failure
Acute liver failure is a rare but serious condition that can develop rapidly, sometimes in just 2 days. When the liver is severely damaged, its many functions are impaired. The outcome of the disease may be decided within 48 to 72 hours of diagnosis. Possible outcomes are liver recovery, need for liver transplantation, or death. See Box 35-1 for causes. Box 35-2 ("Patient Education") teaches patients ways to prevent liver damage and possible liver failure.

Acetaminophen Toxicity
Acetaminophen (Tylenol) overdose is the most common cause of acute liver failure. Acetaminophen should not exceed 3000 mg in a 24-hour period. Prescription drugs containing more than 325 mg of acetaminophen should not be prescribed or taken per Food and Drug Administration (FDA) guidelines. Visit www.knowyourdose.org, an acetaminophen awareness program, for more information and a list of more than 600 medications containing acetaminophen.

CRITICAL THINKING
Carl Young
Carl Young, 23, has returned from a missionary trip in Africa. He reports that during his time there, he sustained a serious laceration that required sutures. Carl also mentions his fondness for seafood and that, since his return, he has had several “feasts” that have included raw oysters. Carl states that since his return, he has lost nearly 8 pounds, is nauseated, has frequent headaches, tires easily, and is very irritable.

1. What information might lead you to suspect hepatitis A infection? Hepatitis B infection?
2. What precautions should be instituted for Carl until a diagnosis is made?
3. What health care team members in addition to nursing will be beneficial to Carl’s care?
4. What patient-centered care actions might you implement to help Carl improve his nutrition?
5. What medications should Carl avoid?
6. What information should be included in a teaching plan related to hepatitis for Carl?

BE SAFE!
You should understand how to monitor the 24-hour dosage of acetaminophen taken by a patient. Look back at the previous 24-hour timeframe from the current time and add up the dosage of any acetaminophen taken alone and in combination drugs. This is a floating 24-hour period, not shift times or a calendar day. The acetaminophen dose should not exceed 3000 mg in a 24-hour period. Also teach the patient how to do this.
Signs and Symptoms
Initial symptoms of liver failure—fatigue, gastrointestinal (GI) upset, and diarrhea—are vague and make detection difficult. As the condition worsens, symptoms become more severe: jaundice, hepatic encephalopathy, bleeding, and abdominal distention. The patient may suddenly lapse into an extremely serious illness, starting with confusion and progressing to coma. In a matter of hours, on x-ray, the liver shows a rapid reduction in size, a typical sign of onset of acute liver failure. In addition, there is a sudden elevation of liver enzymes, ALT, aspartate aminotransferase (AST), and bilirubin. Prothrombin time is elevated, with marked elevation being an ominous sign. Potassium and blood glucose levels drop.

Therapeutic Measures
Treatment is directed toward stopping and reversing the damage to the liver. The patient needs intensive amounts of supportive care. Maintaining the airway (head elevated 30°, NPO [nothing by mouth], nasogastric [NG] tube, endotracheal intubation) is important as encephalopathy progresses. An attempt is made to put the liver completely at rest. The patient is on bed rest. Stimulation is a voided. Most medications are discontinued because they are metabolized by the liver. Dialysis may be ordered if the liver damage results from an overdose of a hepatotoxic substance to filter the substance from the blood. Nutrition may be provided via enteral or parenteral nutrition. Lactulose, neomycin, magnesium citrate, or sorbitol may be given to decrease ammonia levels (see later section on hepatic encephalopathy). If a liver transplant is needed, an otherwise healthy patient may be a priority organ recipient, depending on age and whether the patient is alcohol dependent.

Nursing Process for the Patient With Acute Liver Failure
Nursing care of the patient with acute liver failure is the same as for the patient with cirrhosis, which is discussed next.

Cirrhosis
Cirrhosis is the progressive, irreversible replacement of healthy liver tissue with scar tissue. It is caused by chronic liver disease. In 2010, chronic liver disease/cirrhosis was the 12th leading cause of death in the U.S. population (Murphy, Xu, & Kochanek, 2013). It occurs more commonly among men than women (“Cultural Considerations”). There are a variety of causes of cirrhosis (see Box 35-1). Chronic alcohol use is the most common cause of cirrhosis in the United States.

Pathophysiology
Healthy liver cells exposed to toxins become inflamed. Then the liver cells are infiltrated with fat and white blood cells (WBCs) and are replaced by fibrotic tissue. The liver makes some repairs. But if the damage continues over many years, and an increasing number of liver cells are replaced with fatty tissue and scar tissue, cirrhosis can develop. Liver regeneration continues abnormally, disrupting the lobes of the liver and creating nodules. The liver becomes hardened and lumpy. Early in the disease, the liver is enlarged, firm, and hard from the inflammatory process. Blood flow through the liver becomes impaired due to the nodules, resulting in portal venous hypertension. Later, the liver shrinks and is covered with gray connective tissue. As the disease progresses, liver function is impaired and after many years cirrhosis can lead to chronic liver failure.

Signs and Symptoms
Initially, symptoms are not usually seen with cirrhosis. As liver function becomes impaired, symptoms may begin to be seen. They include anorexia, nausea, vomiting, weight loss, and fatigue, which is due to decreased metabolic function of the liver. Jaundice may be present. The patient’s skin may be dry from bile products deposited in the skin. The patient may report severe pruritus (itching). The liver may be...
enlarged, firm, and tender. Laboratory values reflect progressive loss of liver function. As cirrhosis progresses, signs and symptoms of increasing loss of liver function and complications related to the increasing loss of function develop (Fig. 35.2, Table 35.3).

Complications

Complications of cirrhosis include blood clotting defects, portal hypertension, ascites, hepatic encephalopathy, and hepatorenal syndrome.

CLOTTING DEFECTS. Blood clotting defects may develop because of impaired prothrombin and fibrinogen production in the liver. Furthermore, the absence of bile salts prevents the absorption of fat-soluble vitamin K, which is essential for some blood clotting factors. Patients with cirrhosis have a tendency to bruise easily and can develop disseminated intravascular coagulation or hemorrhage.

PORTAL HYPERTENSION. Portal hypertension is persistent blood pressure elevation in the portal circulation of the abdomen. Liver damage causes a blockage of blood flow in the portal vein. Increased resistance from delayed drainage causes enlargement of the visible abdominal veins around the umbilicus (called caput medusae), rectal hemorrhoids, enlarged spleen (spleenomegaly), and esophageal varices (dilated veins; Fig. 35.3).

The most serious result of portal hypertension is bleeding esophageal varices. The walls of the esophageal veins are thin and tear easily. Varices usually develop from the fundus of the stomach upward and may extend into the upper esophagus. The blood-filled, thin-walled varices may tear easily from sudden excessive pressure, such as the intra-abdominal pressure that results from coughing, lifting, or straining, causing severe bleeding.

</table>

Note. ALT = alanine aminotransferase; ALP = alkaline phosphatase; AST = aspartate aminotransferase; IV = intravenous; PT = prothrombin time; RUQ = right upper quadrant.
ASCITES. Ascites is an accumulation of serous fluid in the abdominal cavity. The fluid accumulates from portal hypertension and low production of albumin by the failing liver and aldosterone accumulation. An insufficient amount of albumin causes plasma to seep into the abdominal cavity. The kidneys respond to the decreased circulating blood volume by saving sodium and water. The accumulated fluid causes a markedly enlarged abdomen. The fluid may cause severe respiratory distress as a result of elevation of the diaphragm.

HEPATIC ENCEPHALOPATHY. Hepatic encephalopathy is caused by elevated ammonia, a byproduct of protein metabolism, which disrupts mental status. The damaged liver is unable to make the ammonia water soluble for excretion in the urine. Signs and symptoms of hepatic encephalopathy include progressive confusion; asterixis, or flapping tremors in the hands caused by toxins at peripheral nerves; and fetor hepaticus, or foul breath caused by metabolic end products related to sulfur.

Stages of hepatic encephalopathy and signs and symptoms of the stages are as follows:

• Early: The patient exhibits subtle changes in personality, fatigue, drowsiness, and changes in handwriting (the best assessment for the early stage).
• Stupor and confusion: The patient is often belligerent and irritable and develops asterixis, muscle twitching, hyperventilation, and marked confusion.
• Comatose: The patient gradually loses consciousness and becomes comatose.

With treatment, if ammonia levels decrease, the patient gradually regains consciousness. Hepatic encephalopathy represents end-stage liver failure and has a mortality rate as high as 90% once coma begins.

HEPATORENAL SYNDROME. Hepatorenal syndrome is a secondary failure of the kidneys in some patients with cirrhosis. Symptoms of hepatorenal syndrome include oliguria without detectable kidney damage, reduced glomerular filtration rate (GFR) with essentially no urine output or less than 200 mL per day, and nearly total sodium retention. Albumin and fresh frozen plasma to increase intravascular volume is given while avoiding diuretics.

Therapeutic Measures
Interventions for cirrhosis are to prevent advancement of the disease and treat complications.

ASCITES. Ascites is treated with diuretics such as spironolactone (Aldactone) or furosemide (Lasix), sodium and fluid restriction (800–1000 mL/day), and albumin infusions for severe ascites. Paracentesis can be done to remove accumulated fluid from the peritoneal cavity when the fluid is compromising the patient’s breathing, causing abdominal discomfort, or posing a threat of ruptured umbilical hernia. If large amounts of fluid are removed, albumin may be given to replace lost proteins to prevent fluid shifting.

Ascites can be treated by the placement of a shunt, called a transjugular intrahepatic portosystemic shunt, under fluoroscopy (Fig. 35.4). Access to place the shunt is gained through the jugular vein. A stent is placed to connect the portal vein to the hepatic vein, in the middle of the liver. This reduces portal pressure by allowing blood to bypass the liver and be carried to the heart. It reduces fluid accumulation and aids in reducing the risk of bleeding.

ESOPHAGEAL VARICES. The medical goals for managing bleeding from esophageal varices are to stop the bleeding immediately, maintain normal clotting, and treat infection. Bleeding varices can be treated with vasoconstrictors such as vasopressin, octreotide (Sandostatin), beta blockers or nitrates, and endoscopic variceal ligation (banding) or sclerotherapy to close the varices. Vitamin K, which is often deficient in liver with cirrhosis may show ascites and enlarge gement of the liver. An abdominal ultrasound may show liver enlargement early in cirrhosis or a small liver later in the disease. An esophagogastroduodenoscopy (EGD) detects esophageal varices and bleeding (discussed later in the chapter). A liver biopsy may be done to determine the extent and nature of the liver damage (see Chapter 32).
In emergency cases when other methods are not available, temporary tamponade (application of pressure) of the bleeding varices may be done with a multilumen esophagogastric tube that has a balloon on the end for inflation (Sengstaken-Blakemore tube or Minnesota tube). Complications of esophagogastric tamponade may include aspiration, erosion of the mucosa, perforation, and suffocation, so it is not often used.

HEPATIC ENCEPHALOPATHY. Lactulose may be given by mouth, NG tube, or enema (depending on how alert the patient is) to make the colon contents more acidic. This creates an insoluble form of ammonia that is then excreted in the stool. Neomycin, an intestinal antibiotic, occasionally may be given to reduce colonic bacteria that change ammonium to ammonia. See “Nutrition Notes.”

### Nutrition Notes

#### Supplying Nutrients to Patients With Liver Disease

A registered dietitian may modify the diet daily for patients with serious liver disease. Usually these patients suffer from severe anorexia, as well as nausea, often displaying their best appetites for breakfast.

Restriction of dietary protein was long considered a mainstay in the management of liver disease and hepatic encephalopathy until studies showed the strategy was not only ineffective but possibly harmful (Ambühl, 2011; Bémeur, Desjardin, & Butterworth, 2010).

#### Nutritional Care for Hepatitis Patients

A high-kilocalorie, high-protein, moderate-fat diet is frequently prescribed for hepatitis patients:
- Up to 400 grams of carbohydrate provides energy intake.
- Up to 100 grams of protein promotes healing.
- Up to 35% of kilocalories in fat to use a dense energy source. Emulsified fats in dairy products and eggs may be better tolerated than other fats.
- Up to 3 to 3.5 liters of fluid intake per day.
- Supplemental between-meal feedings may be prescribed.

#### Nutritional Care for Cirrhosis Patients

In general, dietary interventions for patients with stable cirrhosis features these key components:
- Avoidance of alcohol
- Ingestion of four to six meals per day
- Late evening snack to avoid fasting-associated catabolism
- Protein intake of 1.0 to 1.2 grams per kilogram of body weight
- Sufficient kilocalories to avoid muscle catabolism
- Monitored vitamin status and appropriate supplementation
- Sodium restriction based upon ascites level
Weigh the patient on admission and daily limits for the patient. Excess Fluid Volume related to portal hypertension (ascites) the following.

Common nursing diagnoses for patient with cirrhosis include

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.

A complete history and physical assessment are done. Be alert to subjective symptoms of liver dysfunction, such as abdominal pain, anorexia, nausea, severe itching, and dull, aching RUQ pain. Note objective evidence of liver problems, such as jaundice, light-colored stools, ascites, ecchymosis (bruising) of the skin, GI bleeding, and any evidence of alterations in thought processes, such as confusion, disorientation, or inability to make decisions.

Nursing Process for the Patient With Acute Liver Failure and Cirrhosis

Data Collection. A complete history and physical assessment are done. Be alert to subjecti ve symptoms of liver dysfunction, such as abdominal pain, anorexia, nausea, severe itching, and dull, aching RUQ pain. Note objective evidence of liver problems, such as jaundice, light-colored stools, ascites, ecchymosis (bruising) of the skin, GI bleeding, and any evidence of alterations in thought processes, such as confusion, disorientation, or inability to make decisions.

Nursing Diagnoses, Planning, and Implementation.

Common nursing diagnoses for patient with cirrhosis include the following.

Excess Fluid Volume related to portal hypertension (ascites)

Expected Outcome: Fluid volume will be controlled as evidenced by stable weight and abdominal girth within normal limits for the patient.

- Weigh the patient on admission and daily to measure fluid retention.
- Measure and record the patient’s abdominal girth (circumference) daily to monitor ascites. Mark the place where you measured so the same site will always be measured during subsequent assessments.
- Report any weight gain or increase in girth promptly so treatment can be ordered and complications minimized.
- Monitor the patient’s vital signs and lung sounds; report changes and any evidence of difficulty breathing or changes in mental status promptly to detect fluid overload.
- Measure all intake and output to accurately detect fluid overload.
- Maintain a low-sodium diet and order fluid restrictions to reduce fluid retention.
- Administer ordered diuretics as scheduled to reduce fluid volume.
- If IV fluids or albumin have been ordered, assist in careful monitoring of the rate of infusion to prevent or detect fluid overload.

Imbalanced Nutrition: Less Than Body Requirements related to anorexia and impaired metabolism of needed nutrients

Expected Outcome: The patient’s (dry) weight will be within normal limits for height.

- Monitor weight; report unexpected (nonfluid) weight loss so timely intervention can be implemented.
- Monitor serum prealbumin, total protein, vitamin, and mineral levels because these may be better indicators of nutrition if nutritional status is masked by fluid overload in weight measurement.
- Offer frequent mouth care to increase comfort and make food more palatable.
- Make sure that odors and other unpleasant stimuli are eliminated to prevent further worsening of appetite.
- Offer the patient frequent, small, high-calorie meals to reduce feeling of fullness that can occur with larger meals.
- Administer vitamins or supplements as ordered to correct deficiencies.

Pain related to abdominal pressure

Expected Outcome: The patient will state pain level is acceptable.

- Monitor pain level using a 10-point scale and WHAT’S UP? questions to guide treatment.
- Give analgesics as ordered to control pain. Lower doses may be needed for the patient with liver dysfunction.
- Encourage nondrug pain relief activities, such as distraction, imagery, and relaxation to possibly decrease the need for analgesics.

Risk for Disturbed Thought Processes related to elevated ammonia levels

Expected Outcome: The patient will remain alert and oriented to person, place, and time.

- Assess the patient’s level of consciousness and orientation often to allow prompt treatment.
- Assess neuromuscular function by asking the patient to hold his or her arms out straight in front and steady.

Nutritional Care for Patients With Hepatic Encephalopathy

Hepatic encephalopathy is associated with increased serum levels of ammonia caused by the liver’s inability to degrade ammonia to urea. Ammonia is toxic to all cells, including those of the liver and the brain. The goal of nutritional management of patients with hepatic encephalopathy is to promote protein synthesis by supplying ample amounts of amino acids. Only in cases of severe protein intolerance should protein be restricted and then for as short a time as possible with supplemental branched-chain amino acids administered until normal protein intake is resumed.

Complication of Alcoholic Liver Disease: Wernicke-Korsakoff Syndrome

This disorder of the central nervous system, caused by thiamin deficiency, is diagnosed mainly in alcoholics but also occasionally in malnourished patients with no history of alcohol abuse, including women with hyperemesis gravidarum.

Wernicke’s encephalopathy is an acute neuropsychiatric condition caused by inadequate thiamin supplied to the brain. When caused by dietary deficiency, it can usually be successfully treated with oral or subcutaneous thiamin and rarely progresses to Korsakoff’s psychosis, the result of damage to the brain tissue. Thiamin given at this stage will not reverse the effects. These patients display an abnormal mental state in which memory and learning are affected out of all proportion to other cognitive functions in an otherwise alert and responsive patient.

Expected Outcome: The patient will remain alert and oriented to person, place, and time.

- Monitor blood levels of ammonia caused by the liver’s inability to degrade ammonia to urea. Ammonia is toxic to all cells, including those of the liver and the brain. The goal of nutritional management of patients with hepatic encephalopathy is to promote protein synthesis by supplying ample amounts of amino acids. Only in cases of severe protein intolerance should protein be restricted and then for as short a time as possible with supplemental branched-chain amino acids administered until normal protein intake is resumed.

Expected Outcome: The patient will state pain level is acceptable.

- Monitor pain level using a 10-point scale and WHAT’S UP? questions to guide treatment.
- Give analgesics as ordered to control pain. Lower doses may be needed for the patient with liver dysfunction.
- Encourage nondrug pain relief activities, such as distraction, imagery, and relaxation to possibly decrease the need for analgesics.
If asterixis, or liver flap, is present, the patient’s hands will unwillingly dip and return to the horizontal position in a flapping motion due to elevated ammonia.

- Look for changes in the patient’s handwriting because changes can indicate altered neuromuscular function.
- Give lactulose, neomycin, magnesium citrate, or sorbitol as scheduled to decrease serum ammonia levels.
- Be aware that lactulose causes loose stools, and do not withhold the medication when the patient develops diarrhea. Loose stools are a sign that the medication is working, not a reason to withhold it when treating ammonia levels.
- Question giving medications such as sedatives, opioids, and tranquilizers because these can precipitate hepatic encephalopathy.
- Reorient the patient to time and place as needed and helpful to reinforce reality.
- Give simple, clear explanations of care, and give the patient time to understand the explanation because short, simple explanations are easier to process.
- Provide a safe environment for the confused or unsteady patient to prevent injury.

Risk for Ineffective Breathing Pattern related to excess fluid in the abdomen

**Expected Outcome** The patient’s respirations will be even and unlabored, 16 to 20 per minute.

- Assess the patient’s respiratory rate, rhythm, chest movement, skin color, and oxygen saturation frequently to determine if breathing pattern is effective.
- Assist the patient to use an incentive spirometer and to cough gently every 2 to 4 hours to encourage deep breathing and keep airways clear.
- Elevate the head of the patient’s bed so that the patient’s lungs have maximum room for expansion.
- Administer analgesics carefully, as ordered, if pain is causing shallow respirations. Reducing pain with breathing allows for a more effective breathing pattern.
- Reposition the patient at least every 2 hours to ventilate all areas of the lungs.
- Assist with treatments to decrease ascites as ordered to increase room for lung expansion.

Risk for Deficient Fluid Volume related to bleeding esophageal varices or gastrointestinal bleeding secondary to clotting dysfunction

**Expected Outcome** Fluid volume will remain within normal limits without bleeding as evidenced by no signs and symptoms of bleeding, and vital signs within normal limits for the patient.

- Monitor gastric secretions, stool, and urine at least every 8 hours, and report any signs of bleeding. Early identification of bleeding is essential to prompt treatment.
- Monitor blood clotting laboratory studies such as prothrombin time and report any abnormal values to identify risk for bleeding.
- Caution the patient to use a soft-bristle toothbrush and an electric rather than straight razor to avoid injury and bleeding.

- Avoid suctioning the patient if possible because suctioning can cause esophageal varices to bleed.
- Use a small-gauge needle for injections and apply direct pressure to all puncture sites to avoid bleeding.
- Teach the patient to avoid hot, spicy, or irritating foods because these may irritate the esophageal mucosa and increase risk of bleeding.
- Instruct the patient to avoid forceful coughing or nose blowing, straining, vomiting, or gagging if at all possible. Administer medications as ordered to prevent their occurrence. These can increase pressure and risk of bleeding varices.

**Risk for Infection related to impaired immune function**

**Expected Outcome** The patient will be free from infection as evidenced by WBC count within normal limit, afebrile.

- Monitor for signs of infection and report promptly so treatment can begin.
- Be aware that the earliest warning signs of infection may be subtle changes in the patient’s behavior, such as sudden restlessness, an increase in confusion, or irritability. Early recognition is essential to prompt treatment.
- Carefully evaluate laboratory studies such as the WBC count. The WBC count may not elevate or may elevate slowly because the white cell activity is impaired.
- Teach the patient careful hand hygiene and avoidance of people who are ill to prevent exposure to infection.

**EVALUATION.** Nursing care has been effective if the patient is alert and oriented and has no signs of fluid retention, a stable weight appropriate for height, no abdominal pain or pain reported as tolerable using a 10-point scale, a respiratory rate between 16 and 20 respirations per minute with no cyanosis or changes in level of consciousness, no bleeding, no infection, no injuries, and an accurate knowledge of cirrhosis and proper disease management requirements.

**PATIENT EDUCATION.** Teach patients how cirrhosis is affecting their bodies. In particular, patients need to know about portal system hypertension and hepatic encephalopathy. In addition, teach:

- How to observe for and report any confusion, tremors, or personality changes
- The importance of adequate rest and avoidance of strenuous activity
- See “Nutrition Notes”
- The need to use opioids, sedatives, and tranquilizers cautiously due to potential mental function impairment
- The need to promptly report any bleeding; any sign of low potassium, such as muscle cramps, nausea, or vomiting caused by diuretics; changes in mental status, such as confusion or personality changes; changes in weight; and any increase in current symptoms
- The importance of avoiding alcohol
- The importance of frequent follow-up care and laboratory studies
Liver Transplantation

The patient with end-stage liver failure from cirrhosis, hepatitis, biliary disease, metabolic disorders, or hepatic vein obstruction might be evaluated for a liver transplant. The patient will be evaluated for emotional and physical stability and must accept that he or she will be on daily medications for life (“Cultural Considerations”).

After the surgical implantation of a donor liver, the patient must be closely observed for evidence of donor organ rejection. The patient will be on drugs to suppress immune system responses and prevent tissue rejection. Observe the patient for the following signs of impending rejection:

• Pulse greater than 100 beats per minute
• Temperature greater than 101°F (38°C)
• Reports of RUQ pain
• Increased jaundice
• Decrease in bile from the T-tube or change in bile color.

In addition, laboratory studies may show increased serum transaminases (ALT and AST), serum bilirubin, alkaline phosphatase, and prothrombin time. Symptoms of acute tissue rejection usually develop between the 4th and 10th postoperative days. The patient who has received an organ transplant needs extended medical follow-up. Teach the patient to promptly report to the physician any symptoms of infection, bleeding episodes, or RUQ pain.

As a short-term bridge to liver transplant, bioartificial livers with filtering membranes have been used. Under study, for longer term support is hepatocyte transplantation via a splenic artery catheter.

Cancer of the Liver

Cancer of the liver usually results from metastasis from a primary cancer at a distant location. The liver is a likely area of involvement if cancer originated in the esophagus, lungs, breast, stomach, colon, pancreas, kidney, bladder, or skin. For some patients, liver cancer is the primary tumor site. Patients with a history of chronic hepatitis B or C infection, nutritional deficiencies, heavy alcohol use or smoking, and exposure to hepatotoxins have an increased risk for cancer of the liver.

Symptoms of cancer of the liver include encephalopathy, abnormal bleeding, jaundice, and ascites. Laboratory tests show elevated serum alkaline phosphatase. Radiologic examinations may include abdominal radiographs or radioisotope scans, which show tumor growth. Liver cancer is definitively diagnosed with a positive needle biopsy combined with an ultrasound exam of the liver.

Liver cancer is staged upon diagnosis. If found early, surgery can be curative. Rarely, though, is it found early. Care of the postsurgical patient is similar to other abdominal surgery patients. If surgery is not an option, the patient may receive chemotherapeutic drugs by injection directly into the affected lobe of the liver or into the hepatic artery; sorafenib, which slows the spread of cancer cells; or radiation therapy. The overall survival rate for liver cancer is low. (See Chapter 11 for care of patients with cancer.)

DISORDERS OF THE PANCREAS

Pancreatitis

Pancreatitis, inflammation of the pancreas, may be either acute or chronic. The two forms of pancreatitis have different courses and are considered two different disorders.

Cultural Considerations

Jewish law addresses organ transplantation from the perspectives of the recipient, the living donor, the cadaver donor, and the dying donor. If a recipient’s life can be prolonged without considerable risk, transplant is ordained. For a living donor to be approved, the risk to the life of the donor must be considered. One is not obligated to donate a part of himself or herself unless the risk is small. The use of a cadaver for transplant is usually approved if it is saving a life. The nurse may need to help a patient who is Jewish contact a rabbi when making a decision regarding organ donation or transplantation.
Acute Pancreatitis

Pathophysiology

Inflammation of the pancreas appears to be caused by a process called autodigestion. Recall that the pancreas normally secretes digestive enzymes. For reasons not fully understood, pancreatic enzymes can be activated while they are still in the pancreas and begin to digest the pancreas. In addition, large amounts of enzymes are released by inflamed cells. As the pancreas digests itself, chemical cascades occur. Trypsin destroys pancreatic tissue and causes vasodilatation. As capillary permeability increases, fluid is lost to the retroperitoneal space, causing shock. In addition, trypsin appears to set off another chain of events that causes the conversion of prothrombin to thrombin, so that clots form. The patient may develop disseminated intravascular coagulation (see Chapter 28).

Etiology

Acute pancreatitis is most commonly associated with heavy alcohol consumption or gallstones. Alcohol appears to act directly on the acinar cells of the pancreas and the pancreatic ducts to irritate and inflame the structures. Cholelithiasis (gallstones) or cholangitis (inflammation of the bile ducts) can also trigger pancreatitis. Gallstones may plug the pancreatic duct and cause inflammation from excessive fluid pressure on sensitive ducts. The irritant effect of bile itself may cause inflammation. Elevated triglycerides, pancreatic tumors, or, rarely, medications can cause pancreatitis.

Prevention

Caution patients who drink alcohol to stop. Patients with biliary disease need to seek medical treatment for these conditions so that pancreatitis does not develop as a complication.

Signs and Symptoms

Patients with acute pancreatitis are very ill, with dull abdominal pain, guarding, a rigid abdomen, hypotension or shock, and respiratory distress from accumulation of fluid in the retroperitoneal space. The abdominal pain usually is located in the midline just below the sternum, with radiation to the spine, back, and flank. The location and degree of pain indicate the area of the pancreas involved and to some extent the amount of involvement. Respirations are likely to be shallow as the patient attempts to splint painful areas. Eating makes the pain worse.

The patient may have a low-grade fever, dry mucous membranes, and tachycardia. If the primary cause is biliary, the patient may report nausea and vomiting, and jaundice may be evident. The islets of Langerhans in the terminal one-third of the pancreas are usually not impaired.

Complications

It may be useful to think of acute pancreatitis as a chemical burn to the organ. As with other severe burns, death is likely to occur from secondary causes. From the onset of symptoms, cardiovascular, pulmonary (including acute respiratory distress syndrome), and renal failure are the most likely causes of death. Hemorrhage, peripheral vascular collapse, and infection are also major concerns. A purplish discoloration of the flanks (Turner’s sign) or a purplish discoloration around the umbilicus (Cullen’s sign) may occur with extensive hemorrhagic destruction of the pancreas.

Diagnostic Tests

Diagnosis of acute pancreatitis is made when two of these are present: abdominal pain, serum amylase (normal: 80–180 units/dL) and/or serum lipase (normal: 0 to 160 units/L) more than 3 times normal, abdominal imaging is indicative of it. Serum amylase rises quickly and then returns to normal in 3 to 5 days. Serum lipase is thought to be more specific for acute pancreatitis and elevates and stays elevated for a longer period of time. Glucose, bilirubin, alkaline phosphatase, lactic dehydrogenase, ALT, AST, cholesterol, and potassium are all elevated. Decreases are seen in serum albumin, calcium, sodium, and magnesium. Ultrasonography may show pleural effusion from local inflammatory reaction to pancreatic enzymes or a change in the size of the pancreas.

Therapeutic Measures

Early aggressive IV hydration during the first 24 hours for hypovolemia treatment is recommended. In asymptomatic mild acute pancreatitis, oral nutrition is given (“Nutrition Notes”). In severe cases, enteral feeding is maintained (see “Evidence-Based Practice”). A histamine (H2) antagonist can help decrease acid stimulation of pancreatic secretions (Table 35.4). Additional drug orders include electrolytes such as calcium and magnesium to replace losses, short-acting insulin to combat hyperglycemia, and antibiotics to treat sepsis (Table 35.5). Surgery may be needed for debriding necrotic tissue. Abscesses or pseudocysts may need to be drained.

Nutrition Notes

Nourishing the Patient With Pancreatitis

Nutritionally, mild acute pancreatitis can be treated with the following:

- Aggressive hydration with IV fluids
- Nothing by mouth for 48 hours to avoid stimulating the pancreas
- Clear liquids after pain has been controlled and nausea and vomiting end
- Low-fat, soft diet
- Soft to general diet over 3 or 4 days if satisfactory progress

If the disease progresses to severe pancreatitis, the goal of nutritional support is to meet the elevated
Mrs. Samuels, an 85-year-old retired librarian, is admitted to the nursing unit from the emergency department with severe midepigastric pain that radiates to her back. On admission, she is noted to have guarding of the abdomen, and her abdomen is full and tense. Her medical record documents that she had an endoscopic retrograde cholangiopancreatograph (ERCP) 2 days ago for recurrent episodes of RUQ abdominal pain. She has no history of excessive alcohol intake.

1. What is the most common cause of acute pancreatitis? Does Mrs. Samuels fit the description?
2. Why do patients such as Mrs. Samuels have difficulty breathing?
3. Why is Mrs. Samuels at risk for hemorrhage?
4. What laboratory test is most likely to be abnormal in early acute pancreatitis?
5. Why are opioids commonly ordered for acute pancreatitis?
6. Why does the HCP usually order a histamine antagonist?
7. What nutrition orders will likely be given for Mrs. Samuels?

Suggested answers are at the end of the chapter.

**EVIDENCE-BASED PRACTICE**

**Clinical Question**

Does the use of enteral nutrition have outcomes similar to parenteral nutrition in patients with acute pancreatitis?

**Evidence**

A systematic review of literature from 1999 through 2011 to develop guidelines for pancreatitis and nutrition was conducted. Based on the evidence the following guideline was developed: Nutrition support therapy is generally not needed for mild to moderate disease; nutrition support therapy is needed for severe disease. Enteral nutrition is preferred over parenteral nutrition; parenteral nutrition is only used when enteral nutrition is contraindicated or not feasible.

**Implications for Nursing Practice**

Enteral nutrition is a cost-effective method with fewer complications (infection) for providing nutritional support to patients with acute pancreatitis. Being informed about options for nourishment allows nurses to advocate for patient nourishment to promote healing.

**REFERENCE**

**CRITICAL THINKING**

**Mrs. Samuels**

Mrs. Samuels, an 85-year-old retired librarian, is admitted to the nursing unit from the emergency department with severe midepigastric pain that radiates to her back. On admission, she is noted to have guarding of the abdomen, and her abdomen is full and tense. Her medical record documents that she had an endoscopic retrograde cholangiopancreatograph (ERCP) 2 days ago for recurrent episodes of RUQ abdominal pain. 1. What is the most common cause of acute pancreatitis? Does Mrs. Samuels fit the description?
2. Why do patients such as Mrs. Samuels have difficulty breathing?
3. Why is Mrs. Samuels at risk for hemorrhage?
4. What laboratory test is most likely to be abnormal in early acute pancreatitis?
5. Why are opioids commonly ordered for acute pancreatitis?
6. Why does the HCP usually order a histamine antagonist?
7. What nutrition orders will likely be given for Mrs. Samuels?

Suggested answers are at the end of the chapter.

**Chronic Pancreatitis**

Chronic pancreatitis is ongoing pancreatic cellular damage and decreased pancreatic enzyme functioning often following repeated occasions of acute pancreatitis.

**Pathophysiology**

Chronic pancreatitis is a continuous, progressive disease that replaces functioning pancreatic tissue with fibrotic tissue as a result of inflammation. Pancreatic ducts become...

*Note. ALT = alanine aminotransferase; AST = aspartate aminotransferase; I&O = input and output.*
obstructed, dilated, and finally atrophied. The acinar, or enzyme-producing, cells of the pancreas ulcerate in response to inflammation. The ulceration causes further tissue damage and tissue death, and it may cause cystic sacs filled with pancreatic enzymes to form on the surface of the pancreas. The pancreas becomes smaller and hardened, and progressively smaller amounts of pancreatic enzymes are produced.

**Etiology and Incidence**

The major cause of chronic pancreatitis in men is excessive alcohol ingestion that causes repeated attacks of acute pancreatitis. The major cause in women is chronic obstructive biliary disease, which leads to persistent inflammation of the pancreatic ducts. Other conditions known to cause chronic pancreatitis are prolonged malnutrition, cancer of the pancreas or duodenum, and prolonged use of enteral feedings, which can cause atrophy of the pancreas. The usual age for chronic pancreatitis to develop is between ages 45 and 60. The patient’s mean life span is 25 years after the diagnosis of chronic pancreatitis is made. Death is often not related to pancreatic failure.

**Prevention**

Advise patients with acute pancreatitis from heavy alcohol ingestion that abstinence could prevent recurrence of the pancreatitis and prevent the possibility of chronic pancreatitis. Advise all patients with obstructive biliary disease to seek medical treatment for their condition to prevent the progression from acute to chronic pancreatitis. Carefully monitor patients who are unable to feed themselves for nutritionally adequate diets. Monitor routine laboratory values. Report any trend toward reduced functioning of the pancreas.

**Signs and Symptoms**

The signs and symptoms of chronic pancreatitis are less severe than for acute pancreatitis but are long term. The patient’s history will show a pattern of remissions and exacerbations over years. The patient will report epigastric or lower upper quadrant (LUQ) pain, weight loss, and anorexia.

**Complications**

A variety of complications can result from chronic pancreatitis. Abscesses and fistulas may develop when cysts filled with pancreatic enzymes burst into the abdominal cavity, causing severe inflammation and tissue necrosis. Pleural effusion may develop from inflammation just under the diaphragm. Pancreatic enzymes are essential for normal absorption of nutrients from the intestines. Fat intolerance and malabsorption syndrome with fatty stools and diarrhea may develop in response to the limited amount of pancreatic enzymes produced. In addition, biliary obstruction may further complicate fat absorption. As the terminal third of the pancreas becomes in volved and the islets of Langerhans are destroyed, the patient exhibits symptoms of insulin-dependent diabetes mellitus (discussed in Chapter 40).

**Diagnostic Tests**

Serum amylase and serum lipase levels elevate only in acute disease. In chronic pancreatitis, enzymes will be normal or below normal. Fecal fat analysis shows higher than normal amounts of fat. Both computed tomography (CT) and ultrasonography show characteristic pancreatic structural changes such as masses, calcification of ducts, cysts, and change in pancreatic size. ERCP can locate specific obstructions and detect ductal leaks.

**Therapeutic Measures**

Treatment is aimed at promoting comfort and maintaining adequate nutrition (see “Nutrition Notes: Nourishing the Patient With Pancreatitis”). Pain is managed with analgesics. Surgery may be necessary to treat biliary disease, repair fistulas, drain cysts, or repair other damage.

**Nursing Process for the Patient With Pancreatitis**

See the “Nursing Care Plan for the Patient With Acute and Chronic Pancreatitis.”

**Cancer of the Pancreas**

Pancreatic cancer is the fourth leading cause of cancer deaths in the United States, killing more than 38,000 people each year. The incidence of pancreatic cancer has slowly been rising over the past 10 years. Nearly 45,000 new cases of cancer of the pancreas are diagnosed yearly (American Cancer Society, 2013); it most often affects people between ages 65 and 79.

**Pathophysiology**

Most primary tumors of the pancreas are ductal adenocarcinomas and occur in the exocrine (digestive secretion) parts of the pancreas. The tumors in the head and body of the pancreas tend to be large. Cancer of the pancreas spreads rapidly by direct extension to the stomach, gallbladder, and
duodenum. Cancer located in the body of the pancreas usually spreads farther and more rapidly than do masses in the head. Cancer of the pancreas may spread by the lymphatic and vascular systems to distant organs and lymph nodes.

**Etiology**

The cause of pancreatic cancer is associated most commonly with smoking, then dietary factors (obesity, especially during early adulthood; red meat; processed meat), diabetes mellitus, chronic pancreatitis, and heredity. African American males have the highest rate of pancreatic cancer. Protection may be provided with high folate and lycopene fruits and vegetables.

**Signs and Symptoms**

The patient with pancreatic cancer experiences vague symptoms early in the disease. Epigastric or back pain, anorexia, nausea, fatigue, and malaise are early symptoms. Detection is often difficult because of the nonspecific symptoms identified by the patient. Weight loss is the classic sign of pancreatic cancer. The patient may report abdominal pain that is worse at night. The pain is described as gnawing or boring, and it radiates to the back. The pain may be lessened by a side-lying position with the knees drawn up to the chest or by bending over when walking. The pain becomes increasingly severe and unrelenting as the cancer grows. Pruritus is annoying. Depression may be experienced. The patient may report a bloated feeling or fullness after eating. If the cancer obstructs the bile duct, the patient may have jaundice, dark urine, pruritus, and light-colored stools. The patient’s health history may include a recent diagnosis of diabetes mellitus.

**Complications**

Complications may occur before or after surgical treatment. Preoperative complications include malnutrition, spread of the cancer, and gastric or duodenal obstruction. Postoperative complications include infection, breakdown of the surgical site, fistula formation, diabetes mellitus, and malabsorption syndrome. If the patient has had chemotherapy or radiation therapy, complications specific to those therapies can also occur.

Thrombophlebitis is a common complication of cancer of the pancreas. As the tumor grows, by-products of the tumor growth appear to increase the levels of thromboplastic (clotting) factors in the blood, making clotting easier. The potential for thrombophlebitis increases if the patient is confined to bed or has surgery.

**Diagnostic Tests**

Serum alkaline phosphatase, glucose, and bilirubin levels may be elevated. Amylase and lipase are elevated if the cancer has caused a secondary pancreatitis. Blood coagulation tests, such as clotting time, are done. Carcinoembryonic antigen is ordered to confirm the presence of cancer (normal: less than 5 ng/mL).

Abdominal x-rays determine the size of the pancreas and the presence of masses. CT scan, magnetic resonance imaging (MRI), or ultrasonography are done to precisely locate masses in the pancreas. ERCP can be used to visualize the common ducts and to take tissue samples for microscopic analysis. Pancreatic biopsy is necessary for definitive diagnosis of pancreatic cancer. A tissue sample may be obtained by needle aspiration during ultrasonography. This procedure may cause seeding of the tumor along the needle pathway.

**Therapeutic Measures**

The prognosis for pancreatic cancer is poor. Survival time is often 4 to 6 months. If diagnosed early, treatment may be aimed at cure. If the patient’s cancer has progressed to distant involvement of other organs and lymph

## NURSING CARE PLAN for the Patient With Acute and Chronic Pancreatitis—cont'd

### Intervention
Teach the patient and family to self-monitor for symptoms of malabsorption syndrome, such as fatty stools, weight loss, dry skin, or bleeding. **Rationale** Absence of pancreatic enzymes causes problems with digestion of fats, carbohydrates, and proteins. **Evaluation** Does patient verbalize understanding of symptoms of malabsorption to report?

### Nursing Diagnosis: Risk for Ineffective Breathing Pattern related to abdominal pressure and pain

**Expected Outcome:** The patient will have an effective breathing pattern as evidenced by unlabored respirations, 16 to 20 per minute, SaO₂ 95% or greater at all times.

**Evaluation of Outcome:** Are respirations unlabored, 16–20 per minute, SaO₂ 95% or greater?

### Intervention
Assess the patient’s breathing patterns: • Observe respirations for depth, regularity, and rate. • Observe respiratory effort. • Observe for evidence of respiratory distress, such as use of accessory muscles, use of intercostal muscles, SaO₂ less than 95%, and rapid or difficult breathing. **Rationale** Abdominal pressure from inflammation and tissue damage under the diaphragm may cause the patient to take shallow, rapid respirations, which can tire the patient. **Evaluation** Are patient’s respirations 16–20 per minute, unlabored, and regular? Is patient alert and oriented? Has there been a change in the level of patient’s arousal? Does patient exhibit signs of distress?

**Intervention** Administer oxygen as ordered. **Rationale** Oxygen can decrease the amount of effort the patient must expend to breathe. **Evaluation** Does oxygen help patient breathe easier?

**Intervention** Place the patient in an upright or slightly forward-leaning position. **Rationale** Relieves pressure on the diaphragm. **Evaluation** Is positioning effective?

**Intervention** Prepare the patient’s food by opening cartons and lids and cut food into bite-size portions. **Rationale** Decreases the demand for oxygen. **Evaluation** Does patient accept assistance with food preparation?

**Intervention** Teach the patient to move slowly and to take frequent rests. **Rationale** Helps decrease the demand for oxygen. **Evaluation** Does patient tolerate activity?

### Nursing Diagnosis: Risk for Injury related to hemorrhage or fluid and electrolyte imbalances

**Expected Outcome:** The patient will experience no injury during illness.

**Evaluation of Outcome:** Is there evidence of injury? Are signs and symptoms of impending injury recognized and reported early?

**Intervention** Monitor sodium, potassium, calcium, and magnesium levels daily. **Rationale** Electrolyte levels can become imbalanced in pancreatitis. **Evaluation** Do laboratory studies show that patient’s electrolytes are within acceptable ranges?

**Intervention** Evaluate neuromuscular status by checking Chvostek’s/Trousseau’s signs. **Rationale** These are signs of calcium depletion (see Chapter 6). **Evaluation** Are signs of calcium depletion present?

**Intervention** Monitor the patient’s hematocrit, hemoglobin, and blood clotting times frequently. **Rationale** Destruction of the pancreas can result in hemorrhage. **Evaluation** Does patient have any abnormal bruising, bleeding gums, or pink urine?

**Intervention** Observe abdomen and flanks for Cullen’s and Turner’s signs. **Rationale** These are signs of hemorrhage. **Evaluation** Are signs of hemorrhage present?
nodes, treatment is directed at easing symptoms and making the patient more comfortable.

Surgery is the primary treatment. A total pancreatectomy is one option. For tumors in the body and tail of the pancreas, a distal pancreatectomy is done. When the tumor is located at the head of the pancreas, the Whipple procedure is done to remove the head of the pancreas, the lower portion of the common bile duct, most of the duodenum, and possibly parts of the stomach nearby (Fig. 35.6). Potential postoperative problems after the Whipple procedure include failure of the suture lines to hold, causing leakage of pancreatic enzymes and bile into the abdomen; pneumonia or atelectasis from shallow breathing because the incision line is directly under the diaphragm; paralytic ileus; gastric retention or ulceration; wound infection; fistula formation; unstable diabetes mellitus; and renal failure.

Relief of biliary obstruction can sometimes be accomplished by implanting a stent or plastic tube in the common bile duct during an endoscopic procedure. Pain can be reduced by surgical removal of a portion of the greater splanchnic nerve. Chemotherapy and or radiation therapy can be used to shrink or destroy the tumor, treat or prevent metastasis, or provide relief of symptoms if the cancer has become too widespread for surgery. (See Chapter 11 for care of the patient undergoing radiation or chemotherapy.)

**NURSING PROCESS for the Patient With Pancreatic Cancer**

**DATA COLLECTION.** Observe the patient with cancer of the pancreas for evidence of malnutrition and fluid imbalance, including weight loss, inelastic skin turgor, vomiting, fatty stools, and reports of anorexia or nausea. Review laboratory tests, especially blood glucose, liver function studies, and clotting studies. Evaluate the patient every 2 to 4 hours for pain. Observe the skin for bruising, scaling, and yellowing, and question the patient about itching. Evaluate the patient’s mental status for evidence of depression.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.** The patient with cancer of the pancreas will have numerous problems. Interventions for *Imbalanced Nutrition: Less Than Body Requirements* related to inability to digest food, anorexia, nausea, and vomiting, and *Pain* related to pancreatic tumor or surgical incision are the same as for patients with pancreatitis and are found in the “Nursing Care Plan for the Patient With Acute and Chronic Pancreatitis.” Other care is listed next. Additional interventions for patients with cancer, including psychosocial interventions, can be found in Chapter 11.

**WORD • BUILDING •

*pancreatectomy: pancreat—pancreas + ectomy—excision*
Chapter 35   Nursing Care of Patients With Liver, Pancreatic, and Gallbladder Disorders

Risk for Deficient Fluid Volume

**EXPECTED OUTCOME:** The patient will have adequate fluid volume as evidenced by stable vital signs, elastic skin turgor, and moist mucous membranes.

- Monitor the patient’s intake and output carefully. **Low intake increases risk of deficient fluid volume; low output is a sign of deficient fluid.**
- Monitor vital signs. Tachycardia, tachypnea, and low blood pressure may indicate excessive fluid loss.
- Monitor laboratory values, especially serum sodium, potassium, calcium, and chloride levels. Report abnormal values. If electrolyte values are low, the physician may order IV replacement solutions.
- Report low serum albumin level (normal is 3.4–4.8 g/dL) and assist with monitoring IV albumin therapy if ordered. **Low albumin places the patient at risk for fluid imbalances.**
- Carefully observe the patient for signs of blood loss that may indicate abnormal bleeding:
  - bruising, bleeding gums, or pink-tinged urine
  - Cullen’s sign (bluish discolorations around the umbilicus)
  - Turner’s sign (bluish discolorations on the flanks)
  - Bleeding at incision and drain sites and in drainage tubing
- Teach the patient to use a soft-bristle toothbrush and electric razor rather than a straight razor to reduce risk of injury and bleeding.
- Administer vitamin **K** as ordered to replace deficiency and to reduce risk for bleeding.

Risk for Impaired Tissue Integrity related to itching and to leaking around drainage tubes

**EXPECTED OUTCOME:** The patient’s skin will remain intact.

- Monitor the patient for reports of itching because scratching can cause a break in the skin.
- Help the patient keep fingernails short to reduce damage to skin with scratching.
- Provide frequent skin care with products free of soap or alcohol to prevent further dryness and itching.
- Protect skin around drains with skin-protective barrier products and ostomy bags to prevent skin damage.
- Apply products such as calamine lotion as ordered to decrease itching.
- Exercise special care of any drains to prevent unnecessary tension that may cause suture to give way.
- Keep all drains patent, and keep drainage tubing and bags free from kinks to prevent fluid leakage onto the skin.
- Place the patient in semi-Fowler’s position to help with gravity drainage and reduce risk of fluid leakage.

**EVALUATION.** The plan of care for the patient with pancreatic cancer is successful if the patient maintains body weight within 5% of normal body weight and experiences no nausea or vomiting; states that pain remains tolerable at 2 or less on a pain scale of 0 to 10; has urinary output greater than 30 mL/hr elastic skin turgor, moist mucous membranes, pulse and blood pressure within 10% of patient’s baseline, no sudden, excessive abdominal pain or rigidity, and incisions heal at the expected rate; demonstrates the appropriate self-care procedures for tubes, drains, dressings, and medication administration; and states the signs and symptoms of complications that are to be reported immediately.

**PATIENT EDUCATION.** Teach the patient and family self-care measures such as blood glucose monitoring, insulin administration, signs and symptoms of hyperglycemia and hypoglycemia (see Chapter 40), and the regimen for pancreatic enzyme replacement. Instruct the patient on how to manage dressing changes if he or she is to be discharged with tubes or drains. Patient and family should know the signs and symptoms of hemorrhage, gastric ulceration, infection, and fistula formation. A patient being cared for at home should have a referral for hospice care or home nursing care.

For more information, visit the National Pancreas Foundation at [www.pancreasfoundation.org](http://www.pancreasfoundation.org).

**DISORDERS OF THE GALLBLADDER**

**Cholecystitis, Cholelithiasis, and Choledocholithiasis**

Gallstones and inflammations of the gallbladder and common bile duct are the most common disorders of the biliary system.

**Pathophysiology**

**Cholecystitis** is an acute or chronic inflammation of the gallbladder. It is most often a response to obstruction of the common bile duct resulting in edema and inflammation. Bacteria can invade stagnant bile and add to the inflammation and irritation of the gallbladder. Chronic cholecystitis may be the result of repeated attacks of acute cholecystitis or chronic irritation from gallstones. The gallbladder then becomes fibrotic and thickened and does not empty easily or completely. This is a risk factor for gallbladder cancer.

**Cholelithiasis** is the formation of gallstones in the gallbladder that are most often composed of cholesterol in the United States. They can be asymptomatic for decades. **Choledocholithiasis** refers to gallstones within the common bile duct. Gallstones form when bile becomes supersaturated with a substance such as cholesterol, which then crystallizes, forming sludge with continued enlargement to form stones. Another type of gallstone is a pigment stone. Pigment stones are composed of calcium bilirubinate, which occurs when free bilirubin combines with calcium.

**• WORD • BUILDING •**

cholecystitis: chole—bile + cyst—bladder + itis—inflammation
cholelithiasis: chole—bile + lith—stone + itis—condition
choledocholithiasis: chole—bile + docho—duct + lith—stone + itis—condition
Complications of cholecystitis include cholangitis (inflammation of the bile ducts), necrosis or perforation of the gallbladder, empyema (a collection of purulent drainage in the gallbladder), fistulas, and adenocarcinoma of the gallbladder. A major complication of choledocholithiasis is acute pancreatitis if the pancreatic duct is obstructed.

Diagnostic Tests

An ultrasound of the gallbladder is the classic test done to detect stones, inflamed walls of the gallbladder, and dilated bile ducts.

Etiology and Incidence

CHOLELITHIASIS. Gallstones occur most in women, from aging, obesity, pregnancy, stasis of bile, fasting, medications, and heredity. Stasis may be caused by a decreased gallbladder-emptying rate, a partial obstruction in the common duct, or pregnancy. Excessive cholesterol intake combined with a sedentary lifestyle is linked to an increased incidence of cholelithiasis, as are hemolytic blood disorders such as sickle cell disease and bowel disorders such as Crohn’s disease. After age 50, the rate of gallstones is about the same for men and women (“Cultural Considerations”).

CHOLECYSTITIS. Cholelithiasis is responsible for most cases of cholecystitis, or inflammation of the gallbladder.

Signs and Symptoms

Signs and symptoms of cholecystitis and cholelithiasis are similar. Subjective symptoms include epigastric pain, RUQ tenderness, nausea, and indigestion, especially after eating foods high in fat. Objective symptoms include evidence of inflammation, such as an elevated temperature, pulse, and respiration; vomiting; and jaundice. The patient may have a positive Murphy’s sign, which is the inability to take a deep breath when an examiner’s fingers are pressed below the liver margin. Family history of either cholecystitis or cholelithiasis, dietary habits such as high fat intake or a recent low-fat diet, and reports of flatulence (gas), eructation (belching), nausea, vomiting, or abdominal discomfort after a high-fat meal are common evidence of a gallbladder disorder.

CHOLELITHIASIS. The epigastric pain caused by cholelithiasis may also be called biliary colic. The pain is a steady, aching, severe pain in the epigastrium and RUQ that may radiate back to behind the right scapula or to the right shoulder. The pain usually begins suddenly after a fatty meal and lasts for 1 to 3 hours. If the pain is caused by a stone in the common bile duct (choledocholithiasis), the pain may last until the stone has passed into the duodenum. Jaundice is more commonly present with acute choledocholithiasis because the common bile duct is blocked or inflamed.

CHOLECYSTITIS. The biliary colic caused by cholecystitis typically lasts 4 to 6 hours. The pain is made worse with movement such as breathing. The patient usually has nausea, vomiting, and a low-grade fever with the pain. Heartburn, indigestion, and flatulence are more common with chronic cholecystitis. Patients often report repeated attacks of acute cholecystitis symptoms (Table 35.6).

Cultural Considerations

Gallbladder disease is more common among Mexican Americans. Risk factors include working in occupations such as mining, factories using chemicals, and farming with pesticides. The disease has a lower incidence in blacks in Africa and in blacks living in the Western world. Native Americans have an increased incidence of pancreatic and gallbladder disease. It is unknown how much increased dietary risk factors may contribute to gallbladder disease. The nurse can positively affect the nutritional status of at-risk patients by teaching food preparation practices that use less fat.

CRITICAL THINKING

Donna Stewart

Donna Stewart, a 23-year-old woman, is diagnosed with possible acute cholecystitis. She is 5 feet, 6 inches tall and weighs 138 pounds. She is 4 months pregnant. Her HCP wishes to delay surgery until her inflammation has subsided.

1. What risk factors does Donna have for cholecystitis?
2. What diagnostic tests might be ordered to confirm Donna’s diagnosis of cholecystitis?
3. What considerations should be weighed when scheduling diagnostic tests?
4. What medications can you anticipate that the physician will order for Donna?
5. What type of diet will Donna need to eat after discharge?
6. If the diagnosis of cholecystitis is confirmed, what type of surgical treatment might be ordered?

Suggested answers are at the end of the chapter.
ducts. An ERCP can be done to directly visualize the pancreatic ducts and bile ducts to determine the presence of stones in the common duct and allows the ability to remove stones from the common duct. Further examination may include a radionuclide scan, such as a hepatobiliary iminodiacetic acid scan. For this procedure, the patient will be given an IV injection of a radioactive isotope that is metabolized by the liver and excreted in the bile. The scanning camera then traces the path of the isotope as it travels through the bile ducts, gallbladder, and intestines to identify blockages.

The patient may have an elevated WBC count (normal: 5000–10,000 cells/mm³). If direct bilirubin is elevated (normal: 0.3–1.2 mg/dL), its cause is likely obstruction in the biliary or liver areas. Liver enzymes can rise from hepatic inflammation. Serum amylase and lipase may be elevated if the pancreas is involved or if there is a stone in the common duct.

**Therapeutic Measures**

Treatment of an acute episode of cholecystitis centers on pain control, prevention of infection, and maintenance of fluid and electrolyte balance. Pain control is achieved with analgesics. For itching relief if the patient is jaundiced from bile acid deposits in the skin, colestipol (Colestid) or cholestyramine (Questran, LoCholest) is given. These drugs bind with the circulating bile acids for excretion in the stool. If the patient has nausea and vomiting, an antiemetic may be ordered (see Table 35.4). See “Nutrition Notes.”

**Surgery.** Treatment for cholelithiasis typically involves cholecystectomy (surgical removal of gallbladder) via ERCP.

**Nutrition Notes**

**Modifying the Diet for Patients With Gallbladder Disease**

During an acute attack of cholecystitis, a full liquid diet with minimal fat is usually allowed. For treatment of chronic cholecystitis, the patient is instructed to do the following:

- Correct obesity.
- Avoid troublesome and gas-forming foods (fried foods are worst offenders).
- Decrease dietary fat by (1) selecting skim-milk dairy products, (2) limiting fats or oils to 3 teaspoons, and (3) consuming no more than 6 ounces of very lean meat.

Cholelithiasis has been associated with a long overnight fast that permits concentrated bile to remain in the gallbladder for an extended period. Eating a light bedtime snack or drinking two glasses of water on arising if breakfast is delayed altered this risk factor.

After traditional cholecystectomy, the patient may initially receive nothing by mouth or clear liquids. Then the diet is progressed as tolerated. Following laparoscopic cholecystectomy, patients may receive a general diet immediately.

Later in convalescence, balanced meals should be well tolerated because bile enters the duodenum continuously. Patients who became nauseated and suffered pain after eating certain foods preoperatively, however, may continue to avoid them postoperatively because of the association.
stones may return. Treatment with the dissolution drugs may take months and (Actigall) is used for those who are not surgical candidates.

For large stones or an infected gallbladder, a traditional open cholecystectomy may be required. A T-tube may be inserted into the common duct to ensure that bile drainage is not obstructed (Fig. 35.7). T-tube drainage ranges from 500 to 1000 mL the first day and decreases to 200 mL by the third day. The patient with a traditional cholecystectomy has incisional pain that creates difficulty with coughing and deep breathing postoperatively because deep breathing causes the diaphragm to press on the operative site. Patients are hospitalized for 2 to 3 days with a traditional cholecystectomy.

**EXTRACORPOREAL SHOCK-WAVE LITHOTRIPSY (ESWL).** Extracorporeal shock-wave lithotripsy is done less frequently now due to the availability of laparoscopic cholecystectomy. It uses shock waves to destroy stones in the gallbladder or biliary ducts. Patients who have few cholesterol stones that are not calcified are the most likely candidates for ESWL. After ESWL, the patient is usually put on a course of oral dissolution drugs to ensure complete removal of all stones and stone fragments.

**MEDICATION.** Dissolution of small noncalcified stones (less than 2 centimeters) with the bile acid drugs ursodiol is used for those who are not surgical candidates. Treatment with the dissolution drugs may take 6 months and stones may return.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.** Common nursing diagnoses for the patient with cholelithiasis include pain and risk for deficient fluid volume. Additional nursing diagnoses for the patient with cholelithiasis who has a surgical procedure include risk for impaired skin integrity related to surgical incision and T-tube drainage and risk for ineffective breathing pattern related to abdominal incision.

**Acute Pain related to biliary colic**

**EXPECTED OUTCOME:** The patient will rate pain as 2 or less on a 10-point scale.
- Assess the patient frequently for pain to guide treatment.
- Administer analgesics as ordered to reduce pain.
- Administer antispasmodics or anticholinergics as ordered for biliary colic.
- Assist patient with positioning to assume whatever position provides the most comfort.

**Risk for Deficient Fluid Volume related to anorexia, nausea, vomiting, or excessive tube drainage**

**EXPECTED OUTCOME:** The patient will have adequate fluid volume as evidenced by stable vital signs, elastic skin turgor, and moist mucous membranes at all times.
- Monitor intake and output, daily weights, and skin turgor to monitor fluid balance.
- Monitor T-tube drainage. Carefully observe the T-tube drainage unit to prevent kinking of the tubing. Pressure in the biliary drainage system from poor drainage may greatly increase the patient’s pain and the risk for infection.
- Give antiemetics as needed to control nausea and vomiting.
- Assist with administration of IV fluids and electrolytes as ordered while the patient is on restricted oral intake to maintain hydration.

**Risk for Impaired Skin Integrity related to surgical incision and T-tube drainage**

**EXPECTED OUTCOME:** The patient’s skin will remain intact at all times.
- Inspect the patient’s skin and the sclerae of the eyes for jaundice, and report jaundice or pruritus, to provide treatment to reduce itching injury to skin.
- Inspect the cholecystectomy incision for excessive drainage or evidence of infection such as redness, edema, or warmth, which can irritate and break down skin.

**WORD BUILDING**

liver—pertaining to liver + oscopy—to examine

extracorporeal shock-wave lithotripsy: extra—outside + tripsy—rub or crush
• Change dressings frequently to protect the skin around the incision site from irritating drainage.
• Protect the skin with a skin barrier product or bag such as those used with colostomies if bile is leaking around the T-tube site. An ostomy care nurse (if available) can be consulted for the best choice of dressing. A skin barrier can protect skin from breakdown due to contact with bile.

**Risk for Ineffective Breathing Pattern related to abdominal incision**

**EXPECTED OUTCOME:** The patient will have effective breathing pattern as evidenced by a respiratory rate of 16 to 20 per minute, even, unlabored, depth within normal limits at all times.

• Monitor respiratory rate, depth, and effort, and ability to cough effectively. The high abdominal incision can cause pain with deep breathing and coughing.
• After surgery, encourage the patient to cough and deep breathe at every encounter. Instruct the patient in the proper techniques before surgery and give the opportunity to practice. Deep breathing and coughing after any surgical procedure helps prevent atelectasis and respiratory tract infections.

**EVALUATION.** The plan of care for a patient with cholecystitis or cholelithiasis is successful if the patient reports tolerable pain not greater than 2 on a pain scale of 0 to 10, no weight loss, excessive thirst, urinary output greater than 50 mL/hour; has moist mucous membranes, elastic skin turgor, intact skin with no warmth, redness, swelling, or purulent drainage at the wound site; no jaundice or itching; clear breath sounds; and a normal white blood cell count (Table 35.7).

**PATIENT EDUCATION.** Discharge education focuses on diet. Patients are put on high-protein, low-fat diets. Encourage obese patients to lose weight. After a cholecystectomy, fat should be slowly reintroduced into the diet. Once the duodenum becomes accustomed to a constant infusion of bile, the patient’s individual tolerance for fat becomes the only restriction for diet.

Note. RUQ = right upper quadrant; WBC = white blood cell.
**SUGGESTED ANSWERS TO CRITICAL THINKING**

### Carl Young
1. Foreign travel within the past 2 months, eating raw oysters, fatigue, nausea, and irritability suggest hepatitis A virus infection. Recent possible exposure to materials contaminated with blood or body fluids and fatigue, headache, and nausea suggest hepatitis B virus infection.
2. Careful hand hygiene and standard precautions when handling any body fluids or feces should be instituted.
3. Infectious disease HCP, dietician for nutritional needs, social worker for financial information during recovery period.
4. The nurse should plan to give an antiemetic if Carl is nauseated. Larger meals should be given early in the day, with Carl in an upright or sitting position. The nurse should also ensure that the environment is free of noxious stimulants such as unpleasant odors. The diet should be high calorie, high protein, high carbohydrate, and low fat.
5. Any medication that is known to be hepatotoxic, such as acetaminophen, aspirin, and diazepam (Valium), should be avoided.
6. Carl should be taught that cleanliness, especially with food preparation, is essential; that he should avoid eating raw oysters or raw or undercooked shellfish; that frequent hand washing is crucial; and that alcohol and other liver-toxic substances should be avoided.

### Mrs. Conner
1. Mrs. Conner has a history of poor nutrition that puts her at risk, as does her age.
2. Mrs. Conner may report that she has malaise, nausea, weight loss, a change in bowel habits, and dull, aching RUQ pain.
3. Serum albumin level may be less than 3.2 g/dL. Her prothrombin time will probably be greater than 25 seconds.
4. Esophageal varices and ascites are the two greatest concerns for the patient with portal hypertension.
5. The physician will usually order diuretics, a sodium-restricted diet, and possibly IV albumin infusions.

### Mrs. Samuels
1. The most common cause of acute pancreatitis is heavy alcohol intake. Mrs. Samuels reports no alcohol consumption, but she does have the risk factor of having had a recent ERCP, which may have dislodged a gallstone or irritated the pancreatic duct.
2. Respiratory distress may result from excess fluid accumulation in the retroperitoneal space and from shallow respirations that seek to decrease pressure from the diaphragm on the inflamed pancreas and surrounding tissues.
3. Pancreatitis is similar to a chemical burn and may cause erosion of major blood vessels in surrounding tissue.
4. Serum amylase rises quickly and then returns to normal in 3 to 5 days. Serum lipase is thought to be more specific for acute pancreatitis and elevates and stays elevated for a longer period of time.
5. Opioids are ordered because pain is intense, and pain with anxiety stimulates the autonomic nervous system, which may stimulate greater production of pancreatic enzymes.
7. Enteral nutrition until symptoms (pain) are resolved, then oral nutrition.

### Donna Stewart
1. Some low-fat diets have been linked to the development of cholesterol gallstones, which then irritate the gallbladder and cause inflammation.
2. Donna’s physician might order a white blood cell count, which will be elevated if she has cholecystitis. In addition, the physician may order an ultrasound or radionuclide scan to visualize the gallbladder and its contents and the common bile duct.
3. Donna is 4 months pregnant. Radionuclide scans should be cleared with her obstetrical care provider before being scheduled.
4. You can anticipate that the HCP will order an antibiotic and an analgesic.
5. Donna will need to eat a low-fat diet after discharge. Eventually she may be able to add more fats to her diet as her body adjusts.
6. If the diagnosis is confirmed, Donna will probably have a laparoscopic cholecystectomy unless her HCP decides that she needs a traditional cholecystectomy.
REVIEW QUESTIONS

1. The nurse is planning care for a patient with cirrhosis. For which condition would the nurse place the patient on bleeding precautions?
   1. Encephalopathy
   2. Low vitamin K
   3. Elevated liver enzymes
   4. Hepatorenal syndrome

2. The nurse is caring for a patient with cirrhosis. The nurse would cautiously use sedatives for the patient due to which of the following?
   1. The liver’s ability to synthesize protein is altered.
   2. Sedatives may increase the risk of jaundice.
   3. Sedatives are potentially toxic to the cirrhosis patient.
   4. Sedatives promote the conversion of ammonia to ammonium ion.

3. The nurse is collecting data for a patient with suspected acute hepatitis A infection. Which clinical manifestations would the nurse expect the patient to report?
   1. Brown urine and anorexia
   2. Malaise, lighter colored stools, and pruritus
   3. Headache, nausea, and flulike symptoms
   4. Abdominal pain and jaundice

4. The nurse is caring for a patient with chronic pancreatitis. While reviewing laboratory data to contribute to the plan of care, the nurse would expect an elevation in which laboratory value?
   1. Serum bilirubin
   2. Serum calcium
   3. Serum albumin
   4. Serum amylase

5. A patient with acute pancreatitis is started on early aggressive IV hydration. Which laboratory result indicates the need to consult the dietitian for initial nutritional support?
   1. Potassium 4.2 mEq/L
   2. Sodium 130 mEq/L
   3. Fasting glucose 82 mg/dL
   4. Serum albumin 2.9 g/dL

6. The nurse is planning care for a newly admitted patient with acute pancreatitis. Which patient outcome should receive the highest priority in the plan of care?
   1. Patient expresses satisfaction with pain control.
   2. Patient verbalizes understanding of medications at discharge.
   3. Patient increases activity tolerance.
   4. Patient maintains normal bowel function.

7. The nurse is collecting data for a patient who develops jaundice and dark, amber-colored urine. The nurse recognizes that which of the following is most likely the cause of these manifestations?
   1. Encephalopathy
   2. Pancreatitis
   3. Bile duct obstruction
   4. Cholecystitis

8. The nurse reinforces teaching for a patient after a cholecystectomy who is on a low-fat diet. The nurse will know that the patient understands the diet if which menu items are selected?
   1. Roast chicken, rice, gelatin dessert
   2. Cream of chicken soup, milk, gelatin dessert
   3. Meat loaf, mashed potatoes with small amount of gravy, green beans
   4. Turkey and cheese sandwich on whole-grain bread, apple, milk

9. The nurse is caring for a patient who had an open cholecystectomy 24 hours ago. Which actions should the nurse take to assist the patient to maintain an effective breathing pattern? Select all that apply.
   1. Place in a supine position.
   2. Provide analgesics for pain relief.
   3. Encourage coughing and deep breathing.
   5. Assist with splinting during coughing.
   6. Maintain bed rest for 48 hours after surgery.

10. The nurse is to administer promethazine 12.5 mg intramuscularly and has 50 mg/mL on hand. How many milliliters should be drawn up? Fill in the blank.
    Answer: __________ mL

Answers can be found in Appendix C.

Understanding the Urinary System
KEY TERMS

cystoscopy (sist-TAW-skuh-pee)
dysuria (diss-YOO-ree-ah)
hematuria (HEE-muh-TOOR-ee-ah)
incontinence (inn-CON-tin-ense)
nephrotoxic (NEF-row-TOCKS-sick)
nocturia (knock-TOO-ree-ah)
percutaneous (PURR-kyoo-TAY-nee-us)
pyelogram (PIE-el-oh-gram)
uremia (yoo-REE-mee-ah)
NORMAL URINARY SYSTEM ANATOMY AND PHYSIOLOGY

The urinary system consists of two kidneys and two ureters, the urinary bladder, and the urethra. The kidneys form urine, and the rest of the system eliminates urine. The purpose of urine formation is the removal of potentially toxic waste products from the blood; however, the kidneys have other equally important functions as well:

- Regulation of blood pressure, volume, and composition by the excretion or conservation of water
- Regulation of the electrolyte balance of the blood by the excretion or conservation of minerals
- Regulation of the acid–base balance of the blood by the excretion or conservation of ions such as hydrogen or bicarbonate
- Regulation of all of the above in tissue fluid
- Production of erythropoietin, which then stimulates erythrocyte production in the bone marrow
- Activation of vitamin D, which maintains bone health

The process of urine formation thus helps maintain the normal composition, volume, and pH of blood and tissue fluid.

Kidneys

The bilateral kidneys are located against the posterior wall of the abdominal cavity and are retroperitoneal. The superior portions of both kidneys rest on the inferior surface of the diaphragm and are protected by the lower rib cage. The kidneys are cushioned by surrounding adipose tissue, which is in turn covered by a fibrous connective membrane called the renal fascia. On the medial surface of each kidney is an indentation called the hilus, where the renal artery enters and the renal vein and ureter emerge. The ureter carries urine from the kidney to the urinary bladder.

Internal Structure of the Kidney

A frontal section of the kidney shows three distinct areas: the cortex, medulla, and pelvis (Fig. 36.1).

Blood Vessels of the Kidney

The pathway of blood flow through the kidney is an essential part of the process of urine formation. Blood enters the kidney from the renal artery and exits through the renal vein. Extensive branching within the kidney eventually leads arterial blood to each afferent arteriole. This vessel begins the microcirculation at the nephron, the functional unit of the kidney. The exchanges that take place in the capillaries of the nephrons form urine from blood plasma.

Nephron

Urine is formed in the approximately 1 million nephrons per kidney. The two major parts of a nephron are the renal corpuscle with glomerulus, and the renal tubule with peritubular

capillaries (Fig. 36.2). These are the two sites of exchange between blood plasma and urinary filtrate within the nephron. All parts of the renal tubule are surrounded by the peritubular capillaries, which arise from the efferent arteriole and receive the materials reabsorbed by the renal tubules.

**Formation of Urine**
The formation of urine involves three major processes: glomerular filtration, tubular reabsorption, and tubular secretion.

**Glomerular Filtration**
In glomerular filtration, blood pressure forces water and small solutes out of the glomeruli and into Bowman’s capsules. This fluid is then called renal filtrate (Fig. 36.3).

**Tubular Reabsorption and Secretion**
Exiting the glomerular capsule, renal filtrate then enters the renal tubules. Tubular reabsorption is the recovery of useful materials from the renal filtrate and their return to the blood in the peritubular capillaries (Table 36.1). In tubular secretion, substances are actively secreted from the blood in the peritubular capillaries into the filtrate in the renal tubules.

**The Kidneys and Acid–Base Balance**
Other than exhalation of carbon dioxide by the respiratory system, the kidneys are the organs most responsible for maintaining the normal pH range of blood and tissue fluid. They compensate for the pH changes that are part of normal body metabolism or the result of disease. In acidosis, the kidneys secrete more hydrogen ions into the renal filtrate and return more bicarbonate ions back to the blood. When body fluids become too alkaline, the kidneys return hydrogen ions to the blood and excrete bicarbonate ions in urine.

**Elimination of Urine**
The ureters, urinary bladder, and urethra do not change the composition or volume of urine but are responsible for its elimination.
The fluid that has filtered into Bowman's capsule flows into the renal tubules. The amount of fluid filtered by both kidneys—called the glomerular filtration rate (GFR)—equals about 180 liters each day, which is 60 times more than the body's total blood volume. The body reabsorbs about 99% of this filtrate, leaving 1 to 2 liters to be excreted as urine.

The walls of glomerular capillaries are dotted with pores, allowing water and small solutes (such as electrolytes, glucose, amino acids, vitamins, and nitrogenous wastes) to filter out of the blood and into Bowman's capsule. Blood cells and most plasma proteins, however, are too large to pass through the pores.

3 The fluid that has filtered into Bowman's capsule flows into the renal tubules. The amount of fluid filtered by both kidneys—called the glomerular filtration rate (GFR)—equals about 180 liters each day, which is 60 times more than the body's total blood volume. The body reabsorbs about 99% of this filtrate, leaving 1 to 2 liters to be excreted as urine.

<tr>
<td>Antidiuretic hormone (posterior pituitary)</td>
<td>Promotes reabsorption of water from the filtrate to the blood.</td>
</tr>
<tr>
<td>Atrial natriuretic hormone (atria of heart)</td>
<td>Decreases reabsorption of sodium ions, which remain in the filtrate. More sodium and water are eliminated in urine.</td>
</tr>
<tr>
<td>Parathyroid hormone (parathyroid glands)</td>
<td>Promotes reabsorption of calcium ions from filtrate to blood and excretion of phosphate ions into filtrate.</td>
</tr>
</tbody>
</table>

Specific Gravity
Specific gravity is a measure of the dissolved materials in urine. The specific gravity of urine is 1.002 to 1.035. (The specific gravity of distilled water is 1.000.) The higher the specific gravity, the more dissolved material is present. Specific gravity of urine is a measure of the concentrating ability of the kidneys. They must excrete the waste products that are constantly formed in as little water as possible.

pH
The pH range of urine is 4.6 to 8.0, with an average of 6.0. Diet has the greatest influence on urine pH. A vegetarian diet results in more alkaline urine; a high-protein diet results in more acidic urine.

Constituents
Urine is about 95% water, which is the solvent for waste products and salts. Nitrogenous wastes include urea, creatinine, and uric acid. Urea is formed by liver cells when excess amino acids are deaminated (metabolized) to be used for energy production. Creatinine is a product of metabolism of creatine phosphate, an energy source in muscles. Uric acid results from the metabolism of nucleic acids. Other solutes, such as enzymes and hormones, are present in small quantities.

Aging and the Urinary System
With age, the number of nephrons in the kidneys decreases, often to half the original number by age 70 or 80 (Fig. 36.4). The glomerular filtration rate (GFR) also decreases. This results in part from arteriosclerosis and diminished renal blood flow. The urinary bladder decreases in size, and the tone of the detrusor muscle decreases. This may result in the need to urinate more often or in residual urine in the bladder after voiding. Older adults are also more subject to infections of the urinary tract, and the changes of aging may influence medication therapy for older adults (see “Gerontological Issues”).

**NURSING ASSESSMENT OF THE URINARY SYSTEM**

If the patient has impaired kidney function, complete head-to-toe data collection is needed because kidney disease can affect every system of the body (see Chapter 37).

Health History
Table 36.2 describes questions to ask for a health history, along with the use of the WHAT’S UP? format (Chapter 1) for symptoms.

Physical Examination
Table 36.2 also lists objective data that should be collected.

Pain
Pain in the flank or abdominal areas can be an indicator of renal problems or disease.

**FIGURE 36.4** Aging and the urinary system. This concept map shows effects of the aging process on the urinary system.

**Edema**

Fluid retention can be manifested as edema (excess fluid in tissues). The degree and location of edema is documented (see Chapter 21).

**Daily Weights**

Weight is the best indicator of fluid balance in the body. Patients with renal disease often have fluid imbalances. The patient should be weighed at the same time each day, in the same or similar clothing, and with the same scale. The nurse looks for trends in weight gain or loss. If the patient’s weight is steadily increasing, fluid retention is suspected and should be reported.

**Intake and Output**

The patient with kidney disease is often on a fluid restriction. Intake and output (I&O) should be carefully measured. Intake includes oral, intravenous (IV), irrigation, tube feeding, and other fluids. Output includes urine, emesis, nasogastric effluent, wound drainage if it is copious, and any other drainage.

I&O totals are analyzed and recorded per agency policy, usually every 8 to 12 hours or more often for unstable patients. As with daily weights, the nurse notes trends in retention or loss of fluid to report to the physician. Accurate documentation is vital because the physician may base medication and IV fluid orders on intake and output results.

---

**CRITICAL THINKING**

*Mr. Nolan*

- It is the end of the shift. As you empty Mr. Nolan’s urinary collection bag, you find that it has only 50 mL of concentrated urine in it. What do you do?

*Suggested answers are at the end of the chapter.*

---

**DIAGNOSTIC TESTS FOR THE URINARY SYSTEM**

**Laboratory Tests**

**Urinalysis.** A urinalysis (urine analysis) is a commonly performed diagnostic test for the urinary system, kidney disease, and systemic diseases that may affect the kidneys (Table 36.3).

A urine specimen for routine analysis may be collected at any time of day; however, the first morning specimen is best. First morning specimens are usually concentrated and more likely to contain abnormal constituents if they are present. The specimen should be examined within 1 hour of collection. Urine that cannot be examined promptly should be refrigerated. Urine standing at room temperature longer than 2 hours has more bacteria present, changes in pH, and hemolysis of red blood cells (RBCs). Urine collected for cytology should not be a first morning specimen due to changes in epithelial cells in urine held overnight. Random specimens are used for cytology. If a urinalysis is ordered for a patient with an indwelling urinary catheter, the nurse obtains the sterile urine specimen (see the DavisPlus site for this book).

Composite urine specimens (such as 24-hour urine) are collected over a period of time that may range from 2 to 24 hours. These specimens are usually used to examine the urine for specific components such as glucose, electrolytes, protein, 17-ketosteroids, catecholamines, creatinine, urea nitrogen, and minerals. These specimens may need refrigeration or may have preservatives added to the collection container.

For a composite urine collection, the patient is instructed to urinate and then discard this urine. The time is recorded and becomes the start time of the test. During the designated period all urine voided is saved in the container and kept refrigerated or on ice. Exactly at the end of the time frame, the patient is asked to void, and this is the last amount added to the container. Reminding the patient to save all of the urine is critical for accurate results. Incomplete collections result in inaccurate results. Blood is often drawn from the patient at the end of the test for analysis as part of the test.

**Renal Function Tests**

A number of blood and urine tests reflect kidney function (Table 36.4). If the kidney is not filtering adequately, the serum test values, such as the creatinine and blood urea nitrogen, will be elevated. These tests are useful because they provide information about the severity of a patient’s kidney disease and also the patient’s response to any treatments or medications being used. Renal function test values may still be within the normal range until the glomerular filtration rate is less than 50% of normal.

**Diagnostic Procedures**

Table 36.5 summarizes diagnostic procedures for the urinary system. For explanations of computed tomography (CT) scan, magnetic resonance imaging, and ultrasound testing and routine nursing care, see Appendix A.

**Contrast-Induced Nephropathy**

Contrast media used in diagnostic testing and procedures can be nephrotoxic and cause contrast-induced nephropathy resulting in acute kidney injury within 48 hours of contrast exposure. This condition is serious and can result in death. It is usually asymptomatic with a decline in renal function as shown by a rise in serum creatinine. Treatment is the same as for acute kidney injury (see Chapter 37).

Risk factors are having azotemia (increased creatinine and blood urea nitrogen) and diabetes mellitus-associated renal impairment. Creatinine levels are checked before the procedure and should be monitored afterward. A risk assessment should be done before testing regarding allergies/allergic reactions, diabetes, use of oral metformin (Glucophage), kidney disease, other medical conditions, medications: anti-inflammatory, antibiotics, antifungals, immunosuppressives. When contrast media are used, metformin hydrochloride (Glucophage) must not be given before and for 48 hours after administration of contrast media. Severe lactic acidosis as well as acute kidney injury can occur.

<td>pH</td>
<td>4.6-8.0</td>
<td>pH is greatly affected by food eaten. pH below 4.6 is seen with metabolic and respiratory acidosis. pH above 8.0 is seen when urine has been standing or with infection because bacteria decompose urea to form ammonia.</td>
</tr>
<tr>
<td>Specific gravity</td>
<td>1.002-1.035</td>
<td>Low specific gravity indicates excessive fluid intake or diabetes insipidus. High specific gravity is seen with dehydration. Specific gravity fixed at 1.010 indicates kidney dysfunction. The specific gravity of glomerular filtrate is 1.010.</td>
</tr>
<tr>
<td>Protein</td>
<td>0-18 mg/dL</td>
<td>Persistent proteinuria, creating foamy urine, is seen with damage to the glomerulus. Proteinuria is a significant sign of renal disease. Intermittent protein in urine can result from strenuous exercise, dehydration, or fever. Vaginal secretions may contaminate urine and give a positive reading.</td>
</tr>
<tr>
<td></td>
<td>0-150 mg/24 hr</td>
<td></td>
</tr>
<tr>
<td>Glucose</td>
<td>None</td>
<td>Glucose in urine indicates diabetes mellitus, excessive glucose intake, or low renal threshold for glucose reabsorption.</td>
</tr>
<tr>
<td>Ketones</td>
<td>None</td>
<td>Ketones in urine indicate diabetes mellitus with ketonuria or starvation from breakdown of body fats into ketones. Can also be seen with carbohydrate-free diets, severe diarrhea, dehydration, and vomiting.</td>
</tr>
<tr>
<td>Bilirubin</td>
<td>None</td>
<td>Bilirubin in urine indicates liver disorders causing jaundice. Bilirubin may appear in the urine before jaundice is visible.</td>
</tr>
<tr>
<td>Nitrite</td>
<td>Negative</td>
<td>Nitrites in urine indicate infection. Bacteria in urine convert nitrate to nitrite, which gives a positive reading.</td>
</tr>
<tr>
<td>Leukocyte esterase</td>
<td>Negative</td>
<td>Positive leukocyte esterase in urine indicates infection in urine. It determines the presence of an enzyme released by WBCs in the urine.</td>
</tr>
<tr>
<td>Red blood cells</td>
<td>0-4/hpf</td>
<td>Blood in urine may be caused by kidney stones, infection, cancer, renal disease, or trauma.</td>
</tr>
<tr>
<td>White blood cells</td>
<td>0-5/hpf</td>
<td>WBCs in urine indicate infection or inflammation in the urinary tract.</td>
</tr>
<tr>
<td>Casts</td>
<td>None to occasional hyaline cast</td>
<td>Casts are formed when abnormal urine contents settle into molds of the renal tubules and may be made of protein, WBCs, RBCs, or bacteria. A few hyaline casts may be found in normal urine. The presence of casts usually indicates renal damage or infection.</td>
</tr>
</tbody>
</table>

*Note: hpf = high-power field; RBC = red blood cells; WBC = white blood cells.*

<tr>
<td>Residual urine</td>
<td>Shows amount of urine left in the bladder after voiding.</td>
<td>Bladder ultrasound equipment may be used to determine amount of urine remaining after voiding. Increased residual volume may occur in urethral strictures, sphincter impairment, or neurogenic bladder.</td>
</tr>
<tr>
<td></td>
<td><em>Reference value:</em> Less than 50 mL (increases with age)</td>
<td></td>
</tr>
<tr>
<td>Urinalysis</td>
<td>Used to establish baseline information, confirm or establish a diagnosis, or determine if further testing needs to be done.</td>
<td>May be used to monitor progress of an existing condition or plan a program of care.</td>
</tr>
<tr>
<td>Urine culture</td>
<td>Determines number of bacteria in urine and identifies organism causing urinary tract infection. Sensitivity test also may be ordered to determine most effective antibiotic against offending bacteria. <em>Reference value:</em> Negative if less than 10,000/mL of urine Positive if 100,000 or more/mL of urine An amount less than 100,000 may result from contamination during specimen collection.</td>
<td>Urine should be collected before antibiotic treatment starts to avoid altering results. Catheterized specimen may be ordered to avoid risk of contamination from vagina if female patient is menstruating or patient is incontinent.</td>
</tr>
<tr>
<td>Urine specific gravity</td>
<td>Evaluates the concentration of urine. <em>Reference value:</em> 1.002–1.035</td>
<td>Low specific gravity may occur in patients with diabetes insipidus, glomerulonephritis, or severe renal damage. High specific gravity may occur from diabetes mellitus, high urine glucose level, nephrosis, congestive heart failure, or dehydration.</td>
</tr>
<tr>
<td>Quantitative test for protein</td>
<td>A 12- or 24-hour urine collection is obtained to measure protein. <em>Reference values:</em> Less than 150 mg/24 hours (conventional units) Less than 0.15 g/24 hours (SI units)</td>
<td>Persistent proteinuria is usually seen with glomerular renal disease.</td>
</tr>
<tr>
<td>Creatinine clearance</td>
<td>Measures amount of creatinine cleared from blood in a specified time by comparing amount of creatinine in blood with creatinine in urine. An excellent indicator of renal function. <em>Reference value:</em> 85–135 mL/min</td>
<td>Creatinine clearance is computed in the laboratory and is expressed in volume of blood that is cleared of creatinine in 1 minute. Minimum creatinine clearance of 10 mL per minute is needed to live without dialysis. To carry out the test, urine is collected for a 24-hour period, and a sample for serum creatinine is collected sometime during the 24 hours.</td>
</tr>

<tr>
<td><strong>Cystatin C (Cys C)</strong></td>
<td>Proteinase inhibitor produced by all cells with chromosomes and genetic material at their center at a constant rate, filtered out of blood by the glomerulus, and reabsorbed by tubular epithelial cells.</td>
<td>Cystatin C is a sensitive marker that reflects glomerular filtration rate independent of body weight and height. Cystatin C level increases with impaired renal function.</td>
<td></td>
</tr>
</tbody>
</table>

*Continued*
Understanding the Urinary System

Uric acid

Uric acid is an end product of purine metabolism and the breakdown of body proteins. Uric acid is not as diagnostic as creatinine because many factors can cause an elevated uric acid level. Reference value: 2–7 mg/dL

Blood Chemistry Studies

Sodium (Na⁺)

Extracellular electrolyte regulating blood volume. Reference value: 135–145 mEq/L

Potassium (K⁺)

Intracellular electrolyte excreted by kidneys. Reference value: 3.5–5.5 mEq/L

Calcium (Ca²⁺)

Main mineral in bone and aids in muscle contraction, neurotransmission, and blood clotting. Reference values: 4.5–5.5 mEq/L and 9–11 mg/dL

Phosphorus

Mineral found in bone, teeth, bloodstream, cells. Many functions. Reference values: 2.8–4.5 mg/dL and 0.95–1.45 mmol/L

Bicarbonate (HCO₃⁻)

An alkaline that indicates status of acid–base system. Reference value: 22–28 mEq/L

Magnesium

Found in bone and intracellularly and excreted by the kidney. Reference value: 1.3–2.1 mEq/L

Serum albumin

Plasma protein maintaining oncotic pressure in vascular system. Reference value: 3.5–5.0 g/dL

Elevated uric acid level can be caused by kidney disease, gout (patients with gout metabolize uric acid abnormally), malnutrition, leukemia, use of thiazide diuretics (because of impaired uric acid clearance by the kidney).

Remains within normal range until late stages of renal disease. Decreases with fluid retention (dilutional effect).

In renal disease, K⁺ is one of the first electrolytes to become abnormal. Level greater than 6 mEq/L can lead to muscle weakness and cardiac arrhythmias.

In renal disease decreased reabsorption of calcium leads to bone and mineral disease.

Phosphorus balance is inversely related to calcium balance. Elevated in renal disease.

Most patients with renal disease have metabolic acidosis and low serum HCO₃⁻ levels

Elevated in chronic renal disease. Symptoms of elevated magnesium level include lethargy, nausea, vomiting, and slurred speech.

Low level occurs in nephrotic syndrome and renal disease and leads to edema.

<th>Uses and Possible Abnormal Findings</th>
<th>Nursing Management</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nephrotomogram: Series of x-rays with contrast media creating three-dimensional image of the kidney</td>
<td>Renal cysts, tumors, areas of nonperfusion, renal fractures or lacerations following renal trauma</td>
<td><strong>Precare:</strong> Prepare patient as for a pyelogram, check allergies, creatinine levels before patient receives contrast media. Monitor fluid intake and output before and after test. <strong>Postcare:</strong> Maintain hydration.</td>
</tr>
<tr>
<td>Renal scan</td>
<td>Renovascular hypertension diagnosis; kidney function; renal blood flow; glomerular filtration rate; tubular function; excretion of urine; kidney size and shape; abscesses, cysts, and tumors, which may appear as cold spots because of nonfunctioning kidney tissue; determination of vascular supply to the kidneys in patients with renal trauma, dissecting aneurysm, and other disorders affecting blood flow to the kidneys</td>
<td>Assesses kidneys’ ability to perfuse blood and secrete urine. Usually, no special preparation needed. Determine if any of patient’s medications will interfere with test, such as nonsteroidal anti-inflammatory drugs or antihypertensives. Patient may be asked to drink two glasses of water before test. Level of radiation is very low and produces no side effects. Pregnant and nursing mothers are advised to be cautious. If captopril given monitor for hypotension.</td>
</tr>
<tr>
<td>Renal biopsy</td>
<td>Microscopic examination of kidney tissue for diagnosis or treatment of renal disorder, benign and malignant masses, causes of renal disease, renal transplant rejection, lupus</td>
<td><strong>Precare:</strong> Before biopsy, patient is NPO for 6 to 8 hours. Mild sedative is given. No anticoagulants, CBC, coagulation studies. <strong>During:</strong> Prone position, with sandbag under the abdomen, for biopsy through flank area. Patient instructed to hold breath while needle is inserted to prevent kidney from moving. <strong>Postcare:</strong> Bandage is applied. Patient vital signs and output monitored. Grossly bloody urine, falling blood pressure, and rising pulse are signs of bleeding and are reported immediately. Encourage fluids. Teaching: No heavy lifting for 2 weeks.</td>
</tr>
<tr>
<td>Cystoscopy and pyelogram: Minor surgical procedure with lighted fiberoptic cystoscope</td>
<td>Diagnostic: Inspect inside of bladder, collect urine specimen from either kidney, take x-rays or biopsy growths. <strong>Therapeutic:</strong> Remove small bladder tumors, polyps, stones from bladder/ureters, dilation of ureters, treat enlarged prostate or congenital abnormalities</td>
<td><strong>Precare:</strong> Surgical preparation. <strong>Postcare:</strong> Measure urine output to detect retention from swelling of urinary meatus. Encourage fluid intake. Expect dysuria for 24 hours and initial voidings to be blood tinged. <strong>Complications:</strong> UTI, urine retention, bladder perforation.</td>
</tr>
<tr>
<td>Cystogram or voiding cystourethrogram: X-ray of bladder/lower urinary tract with contrast media or radioisotope instilled into bladder via catheter or cystoscope</td>
<td>Evaluates bladder filling and emptying. Incomplete bladder emptying, distention, reflux, obstruction to urine outflow identified.</td>
<td>No special prep. After the scan, can have slight dysuria and pink urine for 1–2 days. Bright red urine, fever, or persistent discomfort should be reported to physician.</td>
</tr>
</tbody>
</table>

---

**NEW WORD BUILDING**

**cystoscopy:** **cysto**—bladder + **scopy**—to examine
Protective measures continue to be studied. IV hydration with normal saline or a sodium bicarbonate infusion is likely one of the main preventative measures in use. Acetylcysteine (Mucomyst) before and after the procedure is also used.

Renal Biopsy
A renal biopsy diagnoses or provides information about kidney disease. A CT scan or ultrasound is done first to locate the kidney for biopsy. A small section of the renal cortex is obtained for laboratory analysis either percutaneously (local anesthetic, needle through skin) or with a small flank incision. Patients with bleeding tendencies, uncontrolled hypertension, or a solitary kidney generally do not undergo renal biopsy.

Nursing Process for Diagnostic Tests of the Urinary System Assessment
The patient is assessed for baseline understanding testing procedures to plan teaching sessions. Identified contraindications to testing are reported to the health care provider (HCP).

Nursing Diagnoses, Planning, and Implementation
Anxiety related to unfamiliar environment, procedure, diagnostic test, health status, or severity of disease

**EXPECTED OUTCOME** The patient will have reduced anxiety concerning health status or severity of disease before a procedure or test.

- Assess patient for signs and symptoms of anxiety: verbalization, tenseness, tachycardia, elevated blood pressure, facial pallor, and self-focused behaviors. A high level of

fear will interfere with teaching and learning and also diminish cooperation during testing.

- Examine patient’s health beliefs to provide insight into patient behaviors that may affect outcome.

- Acknowledge patient’s anxiety and the perceived threat of the situation to facilitate communication and trust.

- Maintain a calm, supportive, and confident environment and manner when interacting with patient to reduce anxiety.

- Encourage patient to verbalize feelings, concerns, or specific stressors to provide a baseline of information to develop an individualized teaching plan.

- Provide patient with access to timely information regarding outcome of diagnostic testing to facilitate trust and promote comfort.

- Engage support from patient’s family throughout diagnostic testing for patient’s coping.

- Instruct patient in relaxation techniques and facilitate their use to reduce anxiety.

- Respond to patient’s request for assistance as soon as possible to reduce anxiety.

- Reinforce explanations and correct misconceptions the patient has about diagnostic tests or disease condition to facilitate trust and promote comfort.

Acute Pain related to infection, edema, obstruction, or bleeding along the urinary tract or to invasive diagnostic tests

**EXPECTED OUTCOME** The patient will report a decrease in discomfort or pain within 30 minutes of report of discomfort or pain.

- Assess location and level of pain, dysuria, burning on urination, or abdominal or flank pain to provide baseline data to evaluate progression of pain and effectiveness of treatment plan.

- Provide comfort measures to relieve pain.

- Provide analgesics and antispasmodics as prescribed for pain relief.

- Report severe pain to HCP. Severe pain may indicate complications are present or the need for a change in pain control medications.

Impaired Urinary Elimination related to complications from diagnostic tests of the urinary system

**EXPECTED OUTCOME** The patient will maintain urine output greater than 30 mL per hour in the postprocedure period.

- Maintain hydration with ordered IV infusion before and after diagnostic testing to protect kidneys and facilitate contrast removal from the body.

- Monitor fluid intake and output closely to ensure adequate renal function.

- Monitor serum creatinine level to assess for complications from diagnostic testing.

- Observe patient for hypersensitivity reactions to contrast media or injectable materials to help prevent renal complications.

- **WORD BUILDING**

  percutaneous: per—through + cutaneous—skin
Management of Urinary Incontinence

Urinary incontinence is defined as the involuntary leakage of urine and is very common. There are several types of incontinence. The incidence is rising and affects both men and women. Urinary incontinence is often underdiagnosed and underreported because many patients are too embarrassed to talk about the problem. Most patients do not seek treatment until the problem profoundly affects quality of life. With any type of incontinence, the nurse or patient should keep a voiding diary for at least several days to determine when incontinence occurs and to look for any predisposing events. The patient should be referred to a urologist specializing in the area of incontinence or a continence clinic for a careful examination to determine the cause and identify potential medical or surgical treatment. Incontinence that cannot be treated is managed by the use of padding and absorbent products worn by the patient.

Stress Incontinence

Stress incontinence is the involuntary loss of less than 50 mL of urine associated with increasing abdominal pressure during coughing, sneezing, laughing, or other physical activities. Stress incontinence is commonly seen in women after childbirth and after menopause. In men, stress incontinence is associated with prostatectomy and radiation.

Urge Incontinence

Urge incontinence is the involuntary loss of urine associated with an abrupt and strong desire to void. The patient typically reports being “unable to make it to the bathroom in time.” Urge incontinence is the most common type of urinary incontinence in older adults. Patients with stress incontinence or urge incontinence can be taught Kegel exercises to increase perineal muscle tone (Box 36-1, “Patient Education”).

Functional Incontinence

Functional incontinence is the inability to reach the toilet because of environmental barriers, physical limitations, loss of memory, or disorientation. People with functional incontinence are often dependent on others and have no other urinary

Kegel Exercises

Kegel exercises decrease incontinence by strengthening the pubococcygeal muscle, which supports the pelvic or gans. By increasing the tone of this muscle, the patient has an increased ability to tighten the muscle that encircles the urinary meatus and stop the flow of urine. These exercises can also help prevent uterine prolapse, enhance sensation during sexual intercourse, and hasten postpartum healing. It may be used by the older male patient to control dribbling.

1. Establish awareness of pelvic muscle function by instructing the patient to “pull in” the muscles in the perineum as if to control urination or defecation. The muscles of the buttocks, inner thigh, and abdomen are not used to do Kegel exercises.
2. To help identify the correct muscles to tighten, ask the patient to tighten the muscles that control urination. It can be helpful to use an analogy of an elevator: start squeezing at the bottom floor and then squeeze upward to the top floor.
3. Instruct the patient to tight the pelvic muscles for 10 seconds, followed by at least 10 seconds of relaxation.
4. Advise the patient to perform these exercises 30 to 80 times per day. Help devise cues to remind the patient to perform the exercises, such as stopping the stream of urine 10 times each time the patient urinates.

problems. This is a common cause of incontinence in those who are institutionalized.

**Overflow Incontinence**
Overflow incontinence is the involuntary loss of urine associated with overdistention of the bladder. It occurs with acute or chronic urinary distention with dribbling of urine. The bladder is unable to empty normally despite frequent urine loss. Spinal cord injuries or an enlarged prostate may cause this type of incontinence.

**Total Incontinence**
Total incontinence is a continuous and unpredictable loss of urine. It usually results from surgery, trauma, or a malformation of the ureter. Bladder training has been tried and proven ineffective. Often the patient with total incontinence is neurologically impaired. In these situations, the nurse's priority is to keep the patient clean and dry using absorptive products. For the male patient, an external condom catheter can be effective in some situations.

**Nursing Process for the Patient With Stress or Urge Incontinence**
The medical diagnoses of stress and urge incontinence are also nursing diagnoses. Many nursing interventions can help to improve these types of incontinence. See the “Nursing Care Plan for the Patient With Stress or Urge Incontinence and the Nursing Care Plan for the Patient with Functional Incontinence.”

---

**NURSING CARE PLAN for the Patient With Stress or Urge Incontinence**

**Nursing Diagnosis:** Stress Incontinence or Urge Incontinence related to decreased tone of perineal muscles

**Expected Outcomes:** The patient will be continent of urine and will state three actions that can be taken to decrease incidence of stress or urge incontinence.

**Evaluation of Outcomes:** Is the patient continent? Is the patient able to state three actions that can be taken to decrease the incidence of stress or urge incontinence?

**STRESS INCONTINENCE OR URGE INCONTINENCE**

**Intervention** Ask about the history of incontinence. Have patient keep a voiding journal. **Rationale** A journal helps identify the severity and timing of incontinence. **Evaluation** Does patient complete the voiding journal?

**Intervention** Instruct patient on how to perform Kegel exercises (see Box 36-1). **Rationale** Kegel exercises increase perineal muscle tone and help prevent incontinence. **Evaluation** Does patient explain how to perform Kegel exercises?

**Intervention** Work with the patient to incorporate Kegel exercises into normal activities of daily living (e.g., do 10 pelvic muscle contractions during each voiding). **Rationale** An excellent time to perform Kegel exercises is when voiding because the correct muscles are used. **Evaluation** Does patient perform Kegel exercises when voiding or at other cued times during the day?

**Intervention** Encourage patient to drink at least 2000 mL of fluid per day, preferably 3000 mL per day unless medical reason for fluid restriction. **Rationale** Concentrated urine is irritating to the urinary tract and can increase the incidence of urge incontinence and dribbling. **Evaluation** Is urine dilute?

**Intervention** Encourage patient to avoid alcohol and caffeine. **Rationale** Alcohol serves as a diuretic. Caffeine is irritating to the urinary tract. **Evaluation** Does patient explain the need to avoid alcohol and fluids containing caffeine?

**Intervention** Discuss use of and provide small adhesive peripads to wear in underclothing. **Rationale** Peripads provide protection in case of incontinence. **Evaluation** Does patient have and use peripads if desired?

**Intervention** Refer patient to a continence clinic or to a physician specializing in incontinence. **Rationale** Specialists in the area of incontinence can use medical or surgical interventions to decrease incontinence. **Evaluation** Does patient understand what resources are available to further assist with treatment of incontinence?
### NURSING CARE PLAN for the Patient With Stress or Urge Incontinence—cont’d

**Intervention** Refer patient to supportive and educational groups such as National Association for Continence (www.nafc.org). **Rationale** Support groups can help patients deal with the embarrassment of incontinence and learn methods and resources to prevent incontinence. **Evaluation** Does patient know the names and addresses of support groups to help with incontinence?

#### URGE INCONTINENCE

**Intervention** Teach patient to void at frequent intervals (every 2 hours), and then gradually increase the length of time between voidings. **Rationale** By emptying the bladder at frequent intervals, the incidence of urge incontinence can be decreased. **Evaluation** Does patient follow a frequent voiding schedule?

**Intervention** Teach urge inhibition techniques (distraction), such as counting back from 100 by sevens and relaxation breathing. **Rationale** These distraction techniques can help patients reach the bathroom in time to prevent incontinence. **Evaluation** Do distraction techniques help patient prevent incontinence?

---

### NURSING CARE PLAN for the Patient With Functional Incontinence

**Nursing Diagnosis:** *Functional Urinary Incontinence* related to interference with rapid voiding

**Expected Outcomes:** The patient will be continent of urine and will state three measures to increase continence.

**Evaluation of Outcomes:** Is the patient continent of urine? Is the patient able to state three measures to increase continence?

**Intervention** Ask about the history of incontinence. Keep a voiding log of when patient is incontinent. **Rationale** A voiding log helps demonstrate when incontinence is most likely to occur and can help determine the cause of incontinence. **Evaluation** Does the patient cooperate so that a voiding log can be kept?

**Intervention** Determine any acute causes of incontinence, including new onset of urinary tract infection, constipation or impaction, medication effect, or poor fluid intake. **Rationale** These may be readily treatable causes of incontinence. **Evaluation** Does the patient have any easily treatable causes of incontinence?

**Intervention** Determine if clothing is inhibiting timely voiding. If needed, Velcro™ fasteners or sweatshirts and sweatpants might be appropriate. **Rationale** Clothing can be difficult to remove for older adults, resulting in voiding before the clothing can be removed. Clothing can be modified so that it comes off quickly. **Evaluation** Does the patient have easy-to-remove clothing?

**Intervention** Determine if there are any obstacles to reaching appropriate urine receptacle, such as poor lighting, busy bathroom, lack of assistive devices. **Rationale** Obstacles can make it impossible for the patient to reach the voiding receptacle in time to prevent incontinence. **Evaluation** Does the patient have ready access to a voiding receptacle?

**Intervention** Provide appropriate urinary receptacles, such as a three-in-one commode, female or male urinal, or no-spill urinal. **Rationale** Assistive devices can be helpful for the patient to increase continence. **Evaluation** Does the patient need and have access to an appropriate assistive device?

**Intervention** Initiate a voiding schedule of every 2 hours, or base schedule on voiding log. **Rationale** Frequent scheduled voiding using prompting techniques can increase continence. **Evaluation** Does the patient receive help to do bladder training with prompted voiding?

**Intervention** Always assist patient to the toilet when patient first awakens and before sleep. **Rationale** These are the main times when toileting is needed. **Evaluation** Are patient’s toileting needs met?
Management of Urine Retention

Urinary retention is the inability to empty the bladder completely during attempts to void. Many factors can be the cause. It can be acute, with a sudden onset of retention and no urine output, or chronic, with a slower onset of retention of urine and some urine being expelled. Acute retention often results from surgery and is caused by anesthesia, medications, or local trauma to the urinary structures. Acute retention can be a medical emergency causing extreme pain, a large bladder, and the possibility of bladder rupture or acute kidney injury. Chronic urine retention may be related to an enlarged prostate gland, diabetes, pregnancy, a medication effect, strictures, or other causes of obstruction of the urinary tract.

Gentle palpation and percussion of the bladder may be done by the licensed practical nurse/licensed vocational nurse (LPN/LVN) if urine retention is suspected. If the patient has a feeling of fullness but is unable to urinate, the nurse gently palpates the suprapubic area for a full bladder or performs a bedside bladder ultrasound. Normally, the bladder is not palpable. If the fluid-filled bladder is percussed, it sounds dull over the bladder and may extend up to and beyond the umbilicus.

A bladder scan assesses the volume of urine in the bladder (Fig. 36.6). Sound waves estimate the amount of urine in the bladder. It is painless, noninvasive, and requires no patient preparation. The nurse performs this scan at the bedside. It helps guide the need for urinary catheterization, thereby reducing unnecessary catheterizations and associated risks. The bladder scan may be used instead of catheterization (the gold standard for determining urine retention) after the patient urinates to determine the amount of urine remaining in the bladder. Normally the bladder contains less than 50 mL after urination. A residual volume of 150 to 200 mL of urine indicates a need for treatment for urine retention. Bladder scanning may also be used as a tool for incontinent patients to plan their care.

Urinary Catheters

Indwelling Catheters

Indwelling urinary catheters can be inserted into hospitalized patients for various justifiable reasons, such as shock, heart failure, or urinary tract obstruction. The Joint Commission (2014) recommends using indwelling urinary catheters short term and only when necessary because of the high risk of urinary tract infections (UTIs). Urinary incontinence is not a justification for insertion of an indwelling urinary catheter. Indwelling catheters result in UTI the longer they are in place. The incidence of infection is decreased when intermittent straight urinary catheterization is used instead of an indwelling urinary catheter.

With an indwelling urinary catheter, bacteria enter the bladder mainly in two ways: (1) through the outlet at the end of the collection bag contaminating the urine, which is then inadvertently drained back into the bladder, or (2) around the catheter up the urethra and into the bladder. Routine perineal care during the daily bath is sufficient to minimize infection from an indwelling urinary catheter (see “Evidence-Based Practice”). Box 36-2 outlines steps that should be followed to decrease infection in the patient with an indwelling catheter. (See also “Home Health Hints.”)
After an uncircumcised male is catheterized, the foreskin must be properly repositioned over the glans penis and not left retracted to prevent injury. If left retracted, subsequent swelling may make it impossible to pull the foreskin over the glans penis later. This can then cause ischemia of the glans penis, which is an emergency. A physician must be notified immediately and may need to perform an emergency circumcision if the foreskin cannot be properly positioned. Always make sure that the foreskin is positioned properly after catheterization or perineal care.

Box 36-2 Guidelines for Care of the Patient With an Indwelling Urinary Catheter

1. Maintain a closed system. Do not separate the catheter from the tubing of the bag. Instead, steriley collect specimens and irrigate through the specimen port in the tubing.
2. Secure the catheter with tape or fastener as directed. This decreases traction on the catheter and the back-and-forth movements of the catheter that can help bacteria enter the bladder.
3. Encourage fluid consumption to naturally irrigate the catheter, if fluids are not contraindicated.
4. Use aseptic technique when emptying the collection bag by washing hands, wearing clean gloves, and using a clean container for single-patient use to collect the urine.
5. Wash the perineum with soap and water once a day and again if there is any bowel incontinence.
6. Keep the tubing coiled on the bed and positioned to allow free urine flow. Keep the catheter bag below the level of the bladder at all times.
7. Do not clamp catheters. Clamping a catheter results in obstruction and increases risk of infection. Periodic clamping has not been found to be effective in bladder retraining.
8. Replace the urine collection system as required.
9. Remove indwelling catheters as soon as possible.

Intermittent Catheterization

For the patient who is unable to void, the best intervention is intermittent catheterization. A postoperative patient or a patient with a neurologic disorder or urine retention may benefit from intermittent catheterization. It reduces the risk of infection as long as the bladder is not allowed to overfill. A full bladder stretches the muscle fibers, which in turn decreases circulation to the bladder and increases the risk of infection.

Intermittent catheterization involves the use of a straight plastic or rubber catheter that is inserted into the urethra about every 3 hours to empty the bladder. Once the bladder is empty, the catheter is removed. Patients may be taught to do intermittent self-catheterization (ISC) at home. Patients doing ISC may be taught to wash and reuse the same catheter repeatedly when they are in their own environment.

Suprapubic Catheter

After some surgeries of the urinary tract and in some long-term situations, a suprapubic catheter may be used. This is an indwelling catheter that is inserted through a surgical incision in the lower abdomen directly into the bladder.

Nursing care of a suprapubic catheter involves keeping the area clean and dry, changing the dressing when the site is new, and keeping the catheter taped to prevent tension. A skin barrier such as Stomahesive may help prevent the skin from urine leakage. All other care is the same as for any indwelling urinary catheter. See DavisPlus for resources related to the urinary system and its disorders.
Home Health Hints

- The home health nurse should always have a sterile specimen container available. This provides a quick way to get a specimen to the physician's office without the nurse having to obtain the container, saving time and money.
- When catheters become plugged and irrigation fails, families can be taught to take the catheter out. A syringe for removing water from the balloon should be left in the home for this purpose. The family is instructed to avoid cutting the valve stem.
- The family should contact the nurse to reinsert the catheter. For incontinence the patient's bed or chair can be padded with waterproof items such as adult briefs or plastic bags on the mattress. The family must be instructed to notify the nurse immediately if the catheter is plugged or has been removed.
- Not all homes have adequate lighting, which is a must for inserting a catheter. If lighting is inadequate, a caregiver can be asked to hold a flashlight while the nurse inserts the catheter, while respecting the patient’s privacy. The nurse should always have a flashlight available. Having two catheters and catheter trays is also wise in case of a defect or contamination.
- Urine collection bags can be used safely for up to 4 weeks. Cleansing instructions might be provided.
- To encourage fluid intake, urge patient and family to keep a large container of water (1 to 2 quarts) next to the place the patient usually sits. The goal is to drink 2 quarts of water by the end of each day, unless contraindicated by other medical problems. This also simplifies measuring intake. A sports bottle helps to keep water at hand while moving about the home.

CRITICAL THINKING

Mr. Nolan

You should realize that 50 mL of concentrated urine for 8 to 12 hours is not adequate or normal. Further investigation is needed to determine the cause and seriousness of the problem. Some items to assess include the following:

1. Consider Mr. Nolan’s diagnosis. Is he experiencing acute kidney injury? Is he severely dehydrated and retaining water?
2. Ask if anyone emptied Mr. Nolan’s bag earlier in the shift.
3. Look at the trends in Mr. Nolan’s intake and output record. Has his output been decreasing? Is this a change?
4. Has Mr. Nolan been taking in enough fluids?
5. Look at trends in daily weights. Is Mr. Nolan’s weight increasing? Is this an expected finding?
6. Listen to Mr. Nolan’s lung sounds. Check for edema. Do findings indicate fluid retention?
7. Palpate Mr. Nolan’s bladder. Is it distended? Maybe the catheter is blocked.
8. If a problem is identified, the physician should be contacted.

REVIEW QUESTIONS

1. A home health nurse visits a patient who is 82 years old, uses a cane, and is not incontinent. Which of the following interventions should be included in the plan of care, based on an understanding of normal age-related changes of the urinary system, to promote patient safety?
   1. Encourage fluids after 18:00.
   2. Limit fluids to 1000 mL per day.
   3. Provide a nightlight in the bathroom.
   4. Provide adult briefs to absorb dribbling.

2. The nurse is caring for a patient with acute kidney injury. Which of the following actions should the nurse take to obtain the most accurate assessment of fluid balance for the patient?
   1. Document voiding pattern
   2. Obtain daily weight
   3. Review laboratory studies
   4. Observe skin turgor
3. The nurse is caring for a patient who is to have a urine culture and sensitivity done. Which of the following should be included in patient teaching for collecting a midstream clean-catch urine specimen for culture and sensitivity?
   1. A second voided specimen is preferred.
   2. A 24-hour urine specimen is needed.
   3. As soon as the urine starts to flow, it should be collected in a sterile container.
   4. Women should keep the labia separated while voiding.

4. The nurse is caring for a patient who has had a pyelogram with IV contrast. Which of the following care should the nurse provide? Select all that apply.
   1. Maintain nothing by mouth.
   2. Encourage fluids.
   3. Check gag reflex.
   4. Measure urine output.
   5. Position patient prone.
   6. Maintain bed rest for 24 hours.

5. A patient is experiencing stress incontinence with frequent involuntary loss of urine. Which of the following directions would be most appropriate when teaching the patient how to perform Kegel exercises?
   1. “Tighten your rectum at frequent intervals throughout the day.”
   2. “Keep your abdominal muscles tightened; do this every time you stand up.”
   3. “Do at least 20 sit-ups per day.”
   4. “When urinating, stop and start the stream of urine by tightening the perineal muscles.”

6. The nurse is caring for a patient with a urinary catheter. Which of the following is the most important nursing action for the nurse to take to prevent urinary tract infection in this patient?
   1. Force fluids to 4000 mL every 24 hours.
   2. Empty the Foley bag every 4 hours around the clock.
   3. Maintain a closed catheter system.
   4. Wash the perineum every 8 hours.

7. The nurse is documenting the patient’s shift output. What is the patient’s total output as recorded during the 0700 to 1500 shift?
   - 0800 voided 165 mL
   - 1130 voided 450 mL
   - 1300 emesis 42 mL
   - 1500 voided 255 mL
   Answer: __________ mL

8. The nurse is reviewing the urinalysis of a patient. Which of the following are abnormal findings to report to the HCP? Select all that apply.
   1. Blood 7/hpf
   2. Glucose none
   3. Protein 4 mg/dL
   4. White blood cells 11/hpf
   5. Nitrites positive

Answers can be found in Appendix C.
Nursing Care of Patients With Disorders of the Urinary System

MAUREEN MCDONALD

LEARNING OUTCOMES

1. Explain the predisposing causes, symptoms, laboratory abnormalities, and treatment of urinary tract infections (UTIs).
2. Explain the predisposing causes, symptoms, treatment, and teaching for kidney stones.
3. List risk factors and signs and symptoms of cancer of the bladder.
4. List risk factors and signs and symptoms of cancer of the kidneys.
5. Discuss nursing care for a patient with an ileal conduit or continent reservoir.
6. Explain the pathophysiology and nursing care for diabetic nephropathy, nephrosclerosis, hydronephrosis, and glomerulonephritis.
7. Describe the signs and symptoms for patients with acute kidney injury.
8. Describe the signs and symptoms for patients with chronic kidney disease.
11. Discuss nursing care for a vascular blood access site.
12. Plan nursing care for patients on hemodialysis.
13. Plan nursing care for patients on peritoneal dialysis.

urosepsis (YOO-roh-SEP-siss)
Disorders of the urinary tract include a variety of problems involving the kidneys, ureters, bladder, and urethra. These problems may arise from infection, obstructions, cancer, hereditary disorders, and metabolic, traumatic, or chronic diseases. Some may lead to chronic kidney disease (CKD) if not treated or controlled. Infection may be found in three anatomic parts of the urinary tract: the urethra, resulting in urethritis; the bladder, with a diagnosis of cystitis; or the kidneys, with a diagnosis of pyelonephritis. When problems occur with the kidney, homeostasis of the body is affected.

**URINARY TRACT INFECTIONS**

Urinary tract infection (UTI) refers to invasion of the urinary tract by bacteria. Normally, the urinary tract is sterile above the urethra. UTI is the second most common bacterial disease. In the hospital, UTIs are the most common hospital-acquired infection (HAI). Lower UTIs include urethritis, prostatitis, and cystitis. Upper UTIs include pyelonephritis and ureteritis. Infections may result in sepsis or CKD.

**Risk Factors for Urinary Tract Infections**

UTIs are caused most often by an ascending infection, starting at the external urinary meatus and progressing toward the bladder and kidneys. Most UTIs are caused by the bacterium *Escherichia coli*, which is commonly found in feces. Other less common pathogens include *Staphylococcus saprophyticus*, *Klebsiella* spp., and *Enterobacter*. Risk factors for UTI include (a) incomplete emptying of the bladder; (b) contamination in the perineal and urethral area; (c) instruments or tubes inserted into the urinary meatus; (d) reflux of urine because of faulty valves; previous UTIs; (e) anatomical and genetic aspects of females; (f) pregnancy and asymptomatic bacteriuria; and aging.

**Incomplete Bladder Emptying**

Stasis of urine in the bladder can result from obstruction or simply from not voiding frequently enough. Urine overdistends the bladder, decreasing the blood supply to the wall of the bladder, which keeps white blood cells (WBCs) from fighting contamination that may have entered the bladder. The standing urine then serves as a culture medium for bacterial growth. Incomplete emptying of the bladder prevents flushing out of the bacteria and allows bacteria to ascend to higher structures.

**Contamination in Perineal and Urethral Areas**

Contamination in the perineal and urethral areas can be from fecal soiling, from sexual intercourse in which bacteria are massaged into the urinary meatus, or from infection in the area, such as vaginitis, epididymitis, or prostatitis.

**Instrumentation Infection**

Having instruments or tubes inserted into the urinary meatus can cause infection. The most common cause of instrumentation infection is urinary catheterization. Bacteria ascend around or within the catheter, causing infection. Within 48 hours of catheter insertion, bacterial colonization begins. Many patients develop a UTI within 2 weeks of placement of an indwelling urinary catheter.

**Faulty Valves Causing Reflux of Urine**

Faulty valves that do not maintain one-way flow can cause reflux of urine from the urethra to the bladder or the bladder to the ureter. Reflux can be congenital, or it may be acquired as a result of previous infections.

**Previous Urinary Tract Infections**

Previous UTIs are thought to provide a reservoir of persistent bacteria that cause reinfection. Incomplete bladder emptying can precipitate infections as well.

**Female Anatomic and Genetic Differences**

Women are more susceptible to UTIs than men because of the short length of the female urethra and its proximity to the anus and vagina. Some women with recurrent UTIs have a shorter mean distance from the urethra to anus. This can facilitate colonization of the urinary tract. Genetic factors have been found that may play a role in women who have a certain phenotype for developing UTIs.

**Pregnancy**

Pregnant women may have asymptomatic bacteriuria. Untreated, 40% to 50% will develop pyelonephritis. Pregnant women may be prone to infection with group B streptococci. Most commonly, infection occurs in the second and third trimesters.

**Aging and the Urinary Tract**

Older adults have an increased incidence of UTIs due to diminished immune function, diabetes, and neurogenic bladder which fails to completely empty. Aging increases the risk of lower UTIs and may also mask symptoms. UTI is the most common cause of acute bacterial sepsis in patients over age 65. Older men are predisposed to infection because an enlarged prostate obstructs urine flow. In older women, the decline in estrogen can also contribute to the risk of UTI.

**NURSING CARE TIP**

*When caring for a patient at risk for a catheter-related UTI, limit the use of a urinary catheter, use infection control procedures at all times, and discontinue the use of the catheter as soon as possible. Catheter-related UTI is a “never event”—that is, hospitals will not be paid by Medicare for the cost of care provided if this condition occurs during hospitalization.*

**WORD BUILDING**

- **urethritis**: urethra (canal that discharges urine from bladder) + itis—inflammation
- **cystitis**: cyst—closed sac containing fluid + itis—inflammation
- **pyelonephritis**: pyelo—pelvis + neph—kidney + itis—inflammation
**Chapter 37  Nursing Care of Patients With Disorders of the Urinary System**  837

**Signs and Symptoms**

UTIs are characterized by common symptoms of dysuria, urgency, frequency, incontinence, nocturia, hematuria, back pain, and cloudy, foul-smelling urine (Table 37.1). In the older adult, the most common presenting symptom of UTI is generalized fatigue. Atypical symptoms or a change in cognitive functioning, especially noted in patients without dementia, can be seen. A decline in mental status and fever in any patient with an indwelling catheter meets the diagnostic criteria for a UTI.

**Types of Urinary Tract Infections**

**Urethritis**  
Urethritis is inflammation of the urethra that may result from a chemical irritant, bacterial infection, trauma, or exposure to a sexually transmitted infection (STI). Posttraumatic urethritis can occur with common urethral irritants and should not be used by anyone with a history of UTIs. Urethritis can also be caused by spermicidal agents. Gonorrhea and chlamydiosis are STIs that can cause urethritis in men. It is common to have some degree of urethritis in association with bladder or prostatic infections.

Symptoms of urethritis include urinary frequency, urgency, and dysuria. The male patient may have discharge from the penis. A urinalysis or urine culture is done to diagnose urethritis.

The treatment of urethritis is based on the cause. If it is a chemical irritant, it is avoided. If urethritis is caused by bacteria, an antibiotic is prescribed based on the results of a culture. Phenazopyridine (Pyridium), a urinary analgesic, is often used to treat dysuria. The patient should be forewarned that urine will turn orange while taking phenazopyridine. If urethritis was sexually transmitted, it is important that the sexual partner also be treated.

**Cystitis**

Cystitis is inflammation and infection of the bladder wall. It can be due to bacteria, viruses, fungi, or parasites. About 90% of UTIs are caused by *Escherichia coli*. In most cases, the causative organisms first grow in the perineal area and then ascend into the bladder.

Symptoms include dysuria, frequency, urgency, and cloudy urine. Cystitis acquired outside the hospital is diagnosed with a routine urinalysis collected as a midstream, clean-catch specimen. Changes seen in the urinalysis include cloudy urine and the presence of WBCs, bacteria, and sometimes red blood cells (RBCs) in the specimen. Nitrites are usually positive. Some laboratories also examine for leukocyte esterase, which is positive if infection is present in the urine. In complicated UTIs, such as one acquired in the hospital or a repeat infection, a urine culture and sensitivity should be done. Hospital-acquired UTIs are often caused by bacteria that are resistant to the usual antibiotics used for UTIs. A sensitivity test can identify which antibiotics will be effective against the offending organism.

Treatment of uncomplicated cystitis is most often a combination of sulfas medication, such as sulfamethoxazole and trimethoprim (Bactrim, Septra), or nitrofurantoin (Macrodantin).

Complicated cystitis is often treated with ciprofloxacin (Cipro). Other antibiotics may be prescribed depending on the results of the urine culture and sensitivity. Estrogen used as an intravaginal cream may prevent recurrent UTIs in postmenopausal women. The patient is told to finish all prescribed medications, force fluids unless contraindicated, and return for a follow-up urinalysis or culture after the antibiotic course is complete to ensure that the infection is gone.

**Pyelonephritis**

**Pathophysiology.** Pyelonephritis is infection of the renal pelvis, tubules, and interstitial tissue of one or both kidneys. Pyelonephritis usually begins with colonization and infection of the lower urinary tract by means of the ascending urethral route. A preexisting condition is usually present, such as obstruction, strictures, stones, or vesicoureteral reflux. Risk factors include urological surgery, lymphatic infection, urinary stasis, and decreased immunity. Acute pyelonephritis begins in the renal medulla and spreads to the adjacent cortex.

Pathophysiology includes formation of small abscesses throughout the kidney and gross enlargement of the kidney. On occasion, kidney infection is caused by bacteria spreading

**TABLE 37.1 URINARY TRACT INFECTION (URETHRITIS, CYSTITIS, PYELONEPHRITIS) SUMMARY**

| Signs and Symptoms | Urinary urgency, frequency, dysuria  
|                   | Flank pain, fever, chills, costovertebral tenderness  
|                   | Cloudy urine with casts, bacteria, and WBCs  
|                   | Urine positive for nitrates  
| Diagnostic Tests  | Urinalysis culture greater than 100,000 bacteria  
|                   | Elevated WBCs  
|                   | Elevated sedimentation rate  
|                   | Increased neutrophils  
| Therapeutic Measures | Antibiotic therapy sensitive to organism cultured from urine  
|                    | Force fluids  
| Complications      | Pyelonephritis  
|                    | Urosepsis  
|                    | CKD  
| Priority Nursing Diagnoses | Pain  
|                      | Impaired Urinary Elimination: Frequency  
|                      | Ineffective Health Maintenance  

*Note. CKD = chronic kidney disease; WBCs, white blood cells.*
from a distant site through the bloodstream and entering the kidney through the glomerulus. **Urosepsis** is a severe infection of the urinary tract with systemic inflammatory response syndrome. Prompt diagnosis and treatment are essential to prevent septic shock and death.

**SIGNS AND SYMPTOMS.** Symptoms include fatigue, urgency, frequency, dysuria, flank pain, fever, and chills. Costovertebral tenderness on the right or left side (tenderness posteriorly at angle where rib and vertebrae join when struck gently with heel of examiner’s closed fist), which is associated with renal disease, is noted. The urine is cloudy with increased WBCs, bacteria, casts, RBCs, and positive nitrites. In contrast to cystitis, the patient with pyelonephritis is much sicker and shows signs of systemic disease. In acutely ill patients, blood cultures may be obtained.

**DIAGNOSTIC TESTS.** Several tests are helpful to differentiate pyelonephritis from cystitis. With kidney infection, the urinalysis will show casts. Casts are microscopic particles formed in the kidney from abnormal constituents in the urine such as WBCs, RBCs, or pus. The urine specimen will have more than 100,000 colonies of bacteria per milliliter. The presence of casts always indicates a problem in the kidneys. The complete blood cell (CBC) count will show an elevated WBC count. There will also be an increase in sedimentation rate.

**THERAPEUTIC MEASURES.** Treatment of pyelonephritis includes administration of antibiotics based on the results of the culture and sensitivity (Table 37.2). With severe Gram-negative infections, the patient is hospitalized for intravenous (IV) antibiotics. The patient with acute pyelonephritis generally heals completely after treatment and has no lasting kidney damage.

**COMPLICATIONS.** Repeated kidney infections can result in scarring and loss of kidney function, leading to CKD.

**Nursing Process for the Patient With a Urinary Tract Infection**

**Data Collection**

Listen to the patient’s concerns about the diagnosis. Ask about pain on urination, flank pain, or general symptoms of infection, such as fever, chills, and malaise. The patient’s usual pattern of voiding and any urinary frequency, burning, or pain on urination is documented. Note presence of pain in the lower abdomen, flank, or costovertebral angle. Document the presence of a catheter, recent instrumentation, surgery, or other predisposing factors. Inspect the urine for volume, color, concentration, cloudiness, blood, or foul odor. Review urinalysis and culture results.

**Nursing Diagnoses, Planning, and Implementation**

**Acute Pain related to inflammation of the urethra, bladder, and other urinary structures**

**Expected Outcome:** The patient will report relief from pain and discomfort.

- Administer antimicrobial therapy as ordered to relieve pain and discomfort from inflammation and infection.
- Administer antispasmodic agents as ordered to relieve bladder irritability and pain.

- Encourage fluids at 2 to 3 L per day to flush bacteria from urinary tract and promote renal blood flow.
- Apply heat to suprapubic area to relieve discomfort.
- Encourage voiding every 3 hours to empty the bladder; lower bacterial counts, reduce stasis, and prevent reinfection.
- Suggest consuming cranberry juice or capsules to prevent bacteria from sticking on the walls of the bladder (see “Evidence-Based Practice”).
- Teach patient to finish all prescribed medications to prevent recurrent infection.
- Teach patient to avoid cola, coffee, tea, and alcohol because they are urinary irritants.
- Teach patient to empty bladder as soon as urge is felt and after sexual intercourse to flush bacteria out of the body.
- Teach patient to avoid substances such as bubble bath and scented toilet paper, which can be irritants.
- Teach patient to wear cotton underwear to reduce perineal moisture.

---

**EVIDENCE-BASED PRACTICE**

**Clinical Question**

Do cranberries or cranberry juice prevent UTI?

**Evidence**

In a systematic review of studies that compared the use of cranberries containing products to prevent UTI with placebo or nonplacebo controls, it was found that cranberry-containing products are associated with a protective effect against UTIs. Cranberries contain a substance that can prevent bacteria from sticking on the walls of the bladder. Other compounds found in cranberries inhibit the adherence of *E. coli* to the urogenital mucosa (Wang et al, 2012). It was also found that cranberries are effective in reducing the annual number of UTI episodes by 63.9% in clients after renal transplantation (Pagonas et al, 2012).

**Implications for Nursing Practice**

Teach patients that cranberry products might help prevent recurrent UTI.

**REFERENCE**

---

**WORD BUILDING**

**urosepsis:** *uro—* urine + *sepsis*—infection in the blood
Impaired Urinary Elimination related to frequency, nocturia, dysuria, and incontinence

**EXPECTED OUTCOME:** The patient will return to previous voiding patterns.

- Monitor urinary elimination, including frequency, consistency, volume, and color, to identify signs and symptoms of UTI.
- Administer antimicrobial drugs as ordered to eliminate symptoms produced by microbial growth.
- Encourage adequate fluids to prevent infection and dehydration.
- Encourage women to void after sexual intercourse to flush bacteria out of the urethra.
- Teach patient to recognize signs and symptoms of UTI to monitor effectiveness of treatment and detect recurrence.

**Risk for Injury related to sepsis, kidney disease, or kidney injury**

**EXPECTED OUTCOME:** The patient will be free from injury due to sepsis or recurrent infection.

- Administer antimicrobial drugs as prescribed to prevent recurrent infection or complications.
- Monitor intake and output to ensure adequate intake and normal output.
- Monitor patient for signs and symptoms of bacteriuria and bacteremia such as fever, chills, recurrent pain.
- Explain need for follow-up urine culture and imaging studies when indicated by recurrent symptoms.
- Teach need for adequate fluid intake to prevent dehydration and renal impairment.
- Teach signs and symptoms of UTI so patient can detect recurrence or complications.

---

</tr>
</tbody>
</table>
Evaluation
The outcomes have been met if the patient verbalizes relief of pain and discomfort, returns to previous voiding patterns, and is free from injury related to sepsis, CKD, or recurrent infection.

CRITICAL THINKING

Mrs. Milan

Mrs. Milan is a 25-year-old woman who recently had a 3-day weekend getaway with her husband. On Monday she notices that she has symptoms of dysuria, frequency, and urgency. She visits her health care provider (HCP) and is diagnosed with a UTI. She is placed on an antibiotic.

1. What do you think could have predisposed Mrs. Milan to developing a UTI?
2. What should Mrs. Milan be taught to prevent further occurrences of a UTI?
3. What urinalysis findings would you expect for Mrs. Milan?
4. What should you include in her teaching plan based on her therapeutic regimen?

Suggested answers are at the end of the chapter.

Patient Education
It is very important that patients be advised to take the entire prescribed antibiotic until it is gone. It is not uncommon for patients to take medication for several days until symptoms are gone, and then stop. Stopping the antibiotic too early allows the infection to continue. It may become chronic and resistant to antibiotics as a result. In addition to encouraging fluids, cranberry products may be helpful.

Patients who have one UTI commonly develop repeat infections. It is important that such patients receive education to prevent repeated infections of the urinary tract (Box 37-1 and “Nutrition Notes”).

Box 37-1 Patient Education

Preventing Urinary Tract Infection
1. Void frequently—at least every 3 hours while awake.
2. Drink up to 3000 mL of fluid a day if there are no fluid restrictions from the HCP. Preferably drink water.
3. Drink one glass of cranberry juice (10 oz) per day.
4. Take showers; avoid tub baths.
5. Wipe perineum from the front to the back after toileting.
6. Urinate after sexual intercourse.
7. Avoid bubble bath and bath salts, perfumed feminine hygiene products, synthetic underwear, and constricting clothing such as tight jeans.
8. Take medication prescribed for urinary tract infection (UTI) until it is all gone.
9. If UTI is associated with another source of infection, such as vaginitis or prostatitis, ensure that both infections are treated.

UROLOGICAL OBSTRUCTIONS

Urinary tract obstruction is an interference with the flow of urine at any location along the urinary system. It is always a significant problem. The obstruction of urine flow causes dilation and thinning of the renal tubules with eventual atrophy of renal tissues. Renal blood flow is compromised. Eventually renal tissue is destroyed by the compression.

Urethral Strictures

A urethral stricture is a narrowing of the lumen of the urethra caused by scar tissue. Urethral strictures are becoming more prevalent due to the rising incidence of STIs in young adults. Most strictures are acquired from injury or infection. Some strictures are a result of trauma from insertion of catheters or surgical instruments, untreated gonorrhea, and congenital abnormalities.

The patient with a urethral stricture has a diminished urinary stream and is prone to developing UTIs because of obstruction of urine flow. Urethral strictures are often seen in older men. The problem becomes more apparent when attempts to insert a urinary catheter are unsuccessful because of the narrowed lumen.

Initially the treatment of a urethral stricture is mechanical dilation by the urologist, who inserts instruments to stretch open the urethra and then inserts a urinary catheter. If the stricture continues to be a problem after dilation, the area can be surgically repaired (urethroplasty) and a stent inserted.

Nutrition Notes

Urinary Tract Infections
An effective intervention for UTI is increasing fluid intake, both for its flushing effect and to excrete urinary drugs. Instructions to increase fluid intake should specify amounts to consume or the amount of urine to be produced. Patients have developed electrolyte imbalances by overenthusiastically forcing fluids.

• WORD • BUILDING •
urethroplasty: urethra—urethra + plasty—surgical repair
The dilation process can be done at the bedside. This is a painful experience for the patient, and it is helpful and caring to administer pain medication before the procedure. The nursing diagnosis of Acute Pain is very relevant. An indwelling catheter is typically inserted after the dilation, so the nursing diagnosis of Risk for Infection is also present. Patients are taught about UTI prevention (see Box 37-1).

**Renal Calculi**

Renal calculi (kidney stones; one stone is a calculus) are hard, usually small stones that form somewhere in the renal structures (Table 37.3). The stones are masses of crystals and protein that form when the urine becomes supersaturated with a salt capable of forming solid crystals. Diet and lifestyle can account for the prevalence of stones in some patients. Symptoms occur when the stones become impacted in the urinary tract. When stones are found in the kidneys, the condition is called nephrolithiasis (Fig. 37.1).

**Pathophysiology**

Normally, substances dissolved in urine, including urinary salts, are diluted and readily excreted from the body. Calculi are formed when urinary salts are concentrated enough to settle out; the salts often collect and deposit around a nucleus (see Table 37.3). Substances that can serve as a nucleus include pus, blood, dead tissue, a catheter, and crystals. Stones usually grow on the papillae or in the renal tubules, calyces, or renal pelvis. Stones may also form in the ureter or bladder. Stones less than 5 mm are readily passed in the urine.

**Etiology**

Causes of calculi formation include a family history of stones, chronic dehydration (causing more concentrated urinary salts), and infection, because the latter provides a nucleus for stone formation. Additional contributing causes of calcium stones include dietary factors (“Nutrition Notes”) and medications (Table 37.4). Excessive amounts of calcium in the water in some geographic areas may also be a factor. Immobility causes stone formation because of the resulting urinary stasis; in addition, calcium leaves the unstressed bones during immobility, so more calcium is in the blood, which is then filtered through the kidneys. Stones are more common in men than women. A diet high in sodium and animal protein increases the amount of calcium in the urine (hypercalciuria).

and may contribute to the formation of stones. The risk peaks between ages 30 and 50.

**Signs and Symptoms**

Symptoms of renal calculi include excruciating flank pain and renal colic. When a stone is lodged in the ureter, it is common to have pain radiate down to the genitalia. The pain results when the stone prevents urine from draining. Additional symptoms include hematuria from irritation by the stone, dysuria, frequency, urgency, and enuresis. The patient also may have costovertebral tenderness. Some people develop nausea, vomiting, and diarrhea because of the proximity of the GI structures. Table 37.5 summarized the discussion of renal calculi.

**Prevention**

Consult with the HCP and dietitian to determine if any foods should be avoided, depending on the type of stone found. “Nutrition Notes: Renal Calculi” discusses foods that may contribute to calculi development (see also “Cultural Considerations”). Encourage fluid intake to prevent dehydration. Encourage the patient to walk, which promotes the excretion of stones and reduces bone calcium resorption (release). Urocit(r)-K (potassium citrate), which restores chemicals in the urine that prevent crystals from forming to decrease calcium oxalate and uric acid stones, might be prescribed.

**Complications**

The presence of renal calculi increases the risk for UTIs because of obstruction of the free flow of urine. Untreated obstruction of a stone in a ureter or the urethra can also result in:

**Nutrition Notes**

**Renal Calculi**

Concentrated urine enhances the formation of crystals, so sufficient fluid should be consumed to produce 2000 mL of urine per day. About 3000 mL or 13 cups of water per day are needed to produce this amount of urine.

About 80% of kidney stones are composed of calcium oxalate, which led to early prescriptions for low-calcium diets, but it was later found that a high-calcium intake binds dietary oxalate in the gastrointestinal (GI) tract and prevents its absorption, thereby reducing urinary oxalate formation. If a low-oxalate diet is prescribed, a long list of foods may be restricted beginning with spinach, rhubarb, beets, nuts, chocolate, tea, wheat bran, and strawberries.

Uric acid kidney stones can be a complication of gout, which is a disorder of purine metabolism. Purines are end products of digestion of certain proteins and are present in some medications. High-purine foods include organ meats, anchovies, herring, sardines, meat extracts, consommé, and gravies.
in retention of urine and damage to the kidney. This process is called hydronephrosis (discussed later).

Diagnostic Tests

Helical computed tomography (CT) without contrast is the preferred diagnostic test. It requires no contrast agent and has the ability to detect stones in the distal ureters as well as small stones less than 1 to 2 mm. Other tests include an abdominal x-ray or an IV pyelogram, which will identify the anatomic location of the stone. Renal ultrasound may be done to identify a stone in the renal pelvis, calyx, or ureter. This is the preferred test for pregnant women suspected of having a kidney stone. Urinalysis may indicate gross or microscopic hematuria and could indicate abrasion of the urinary tract. The presence of crystals or urinary pH may indicate calculus type. Two consecutive 24-hour urine collections should be done while the patient follows his or her usual diet. The 24-hour urine collection should measure total urine volume, calcium, oxalate, citrate, uric acid, sodium, potassium, phosphorus, pH, and creatinine as well as cystine and magnesium.

Therapeutic Measures

Renal calculi are treated medically if possible. Most small stones are flushed out of the body during urination. Patients can pass stones in the urine if they are 5 mm or smaller. Drinking 2 to 3 quarts of fluids, taking analgesics such as Tylenol or ibuprofen, and perhaps a prescribed alpha-blocker medication (such as tamsulosin [Flomax]) to relax ureter muscles will help pass a small stone.

Patients who develop severe renal colic are usually admitted to the hospital. IV fluids are given to hydrate the patient and help flush the stone out of the body. All urine is strained to detect passage of stones, and pain medication is given. If the patient is unable to pass the stone and infection, impaired renal function, or severe pain continues, intervention is needed. The solubility of stone-forming substances can be changed by altering the pH of the urine. Calcium stones may be treated with thiazide diuretics and allopurinol (Aloprim,

### Cultural Considerations

Recurrence Calculus Development

Filipino immigrants are at high risk for developing renal stones, hyperuricemia, and gout. A shift from a traditional Filipino diet to an American diet increases the occurrence of hyperuricemia, with some older Filipinos developing gout. The nurse may need to assist Filipino patients to identify food choices that will help prevent these conditions.

Caucasians have the highest incidence of kidney stones, followed by Mexican Americans. African Americans have the lowest risk. Prevalence of stones is increased in the southern United States and lowest in the western United States.

Note. BUN = blood urea nitrogen; CKD = chronic kidney disease; KUB = kidney, ureter, and bladder x-ray.

### Word Building

hydronephrosis: hydro—pertaining to water + nephrosis—degenerative change in kidney
Surgical removal may be required for large stones, obstructions, or intractable pain.

**Lithotripsy.** Lithotripsy is the use of sound, laser, or dry shock-wave energies to break the stone into small fragments. Types of lithotripsy include extracorporeal shock-wave lithotripsy (ESWL), electrohydraulic lithotripsy, laser lithotripsy, and percutaneous ultrasonic lithotripsy.

With ESWL, a form of lithotripsy, sedated or anesthetized patients lie down on the lithotriptor with a water-filled device supporting their back. Ultrasonic shock waves are used to break up the stone into sand particles, which are then urinated out over a week with small discomfort or be small enough to be removed. Some lithotripsy procedures do not require submersion and use other means of initiating shock waves (Fig. 37.2). Occasionally, a stent is placed in the ureter to facilitate the passage of the stone fragments. After the procedure, the patient is usually discharged home after being told to increase fluid intake to help flush the sand particles out, strain the urine to catch stone fragments for analysis, and notify the urologist if there are any problems. Blood in the urine is common after lithotripsy. ESWL is most effective with stones that are in the kidney. ESWL may increase the risk of kidney disease or hypertension later in life.

**Surgery for Renal Calculi.** Some patients may need surgery for stone removal. The particular procedure chosen—endoscopic or open surgery—depends on the location of the stone.

Endoscopic procedures for the bladder include cystoscopy for small stones and cystolitholapaxy for larger stones. For cystolitholapaxy, an instrument is inserted through the urethra to the bladder to crush the stone. The stone is then washed out with an irrigating solution. If the stone is lodged in a ureter, the urologist may insert an instrument into the ureter through a cystoscope to crush the stone or use an ultrasonic lithotripsy instrument to break the stone into fragments. Postoperative care following these procedures is similar to care following any cystoscopy (see Chapter 36). The open surgery procedure for stones in the bladder is a cystotomy and for the ureter an ureterolithotomy.

For kidney stones, a percutaneous nephrolithotomy is performed in which a scope is inserted through the skin into the kidney to aid in breaking up the stone and to irrigate the renal pelvis. A nephrostomy tube is often left in place at first to prevent stone fragments from passing through the urinary system. If the stone is very large, a nephrolithotomy may be needed, which involves a surgical incision into the kidney to remove the stone. A pyelolithotomy is done to remove stones lodged in the renal pelvis.

**Nursing Process for the Patient With Renal Calculi**

**Data Collection.** Patients with stones are often in extreme pain and should be monitored for pain. Patients over age 60 should have an abdominal aneurysm ruled out. A health history may identify a family or patient history of previous stone formation. People who have had stones usually have a recurrence. Why would renal colic usually begin suddenly, progress rapidly, and peak over a 30-minute period? Because it occurs as urine attempts to pass the stone. Flank pain may radiate to the genitals. Diminished or absent bowel sounds may progress to an ileus. The patient may also be restless, pale, and lightheaded.

Nursing care of a patient with a renal calculus involves careful measurement of intake and output and observation of urine for abnormalities such as hematuria, pyuria, or passage of a stone. Obstruction may occur at the bladder neck or urethra. With obstruction, anuria (less than 50 mL of urine output daily) or oliguria (less than 400 mL of urine output daily) is noted. This is an emergency situation and must be treated immediately to preserve kidney function. Temperature is monitored for onset of fever, which would indicate infection.

**Word Building**

- Lithotripsy: litho—stones + tripso—breaking stones
- Nephrolithotomy: nephro—kidney + lith—stone + otomy—incision
- Anuria: an—without + uria—urine
- Oliguria: olig—small + uria—urine
Blood pressure may decrease if severe pain causes shock. A special strainer is used to strain all urine for stones. If a stone is found, it is saved for analysis in the laboratory. The patient is also asked about a recent history of infection, diet or activity changes, or other risk factors for renal calculi. If the cause can be identified, teaching can be done to help prevent recurrent calculi.

**NURSING DIAGNOSIS, PLANNING, AND IMPLEMENTATION.**

**Acute Pain related to the presence of, obstruction, or movement of a stone within the urinary system**

**Expected Outcome:** The patient will verbalize the relief of pain or ability to tolerate pain.

- Ask severity, location, and duration of pain using a pain scale. Pain is typically in the flank or costovertebral angle and may radiate to the pelvic, groin, or abdominal area.
- Monitor patency of drains, and catheters. Obstruction of urine flow will increase pain.
- Encourage fluid intake, unless contraindicated, to promote the passage of stone, dilute the urine, and reduce the risk of further stone formation.
- Administer pain medication as ordered to promote comfort.
- Apply heat to flank area to reduce pain and promote comfort.
- Ambulate if possible to facilitate the passage of the stone through the urinary system.
- Strain urine through gauze or strainer to identify stones that may have been passed providing pain relief.

**Risk for Infection related to the introduction of bacteria from obstructed urinary flow and instrumentation**

**Expected Outcome:** The patient will remain infection free.

- Monitor vital signs, and observe for chills, cloudy, foul-smelling urine, or bleeding. Abnormalities may indicate an infection.
- Monitor urine amount, color, clarity, and odor to ensure patency of urinary system or tubes. Foul-smelling or cloudy urine may indicate an infection.
- Encourage fluid intake to flush bacteria and stones and prevent further stone formation.

**Deficient Knowledge related to lack of knowledge about prevention of recurrence, diet, and symptoms of renal calculi**

**Expected Outcome:** The patient will verbalize an understanding of the factors related to the recurrence of renal calculi, infection, and treatment options.

- Note recurrence of renal stones. Recurrence may indicate knowledge deficit.
- Note family history of renal stones and explain relevance to patient. Stones have a higher incidence in patients with a positive family history.
- Determine the relationship between activity and stones. Sedentary lifestyle or limited mobility may increase risk of stone formation.
- Ask the patient’s understanding of possible courses of therapy to treat renal stones to establish baseline knowledge.
- Teach the importance of maintaining a fluid intake of 2 to 3 quarts per day. Low-solute (dilute) urine helps prevent stone formation.

- Teach patient about medications used to prevent recurrence of renal stones:
  - Diuretics (thiazide type) increase tubular reabsorption of calcium, making it less available for calculus formation in the urinary tract.
  - Allopurinol (Zyloprim) reduces uric acid production.
  - Antibiotics prevent chronic UTI, which may precede renal calculus formation.
- As applicable, teach patient about management of stones. Most stones pass spontaneously. There may be pain, nausea, and vomiting. Medical management consists of fluids, pain management, and antibiotics. Mechanical interventions with percutaneous catheters and nephroscopic procedures, lithotripsy, or surgery can be used to eliminate stones.

**EVALUATION.** Outcomes have been achieved if the patient remains comfortable, free from infection, and gains understanding about prevention of the reoccurrence of renal stones.

**Hydronephrosis**

Hydronephrosis is distention of the renal pelvis and calices. This condition results from untreated obstruction of urine flow in the urinary tract. The kidney enlarges as urine collects in the pelvis and kidney tissue. Hydronephrosis is usually treatable once the condition is detected.

Obstruction of urine flow can result from a stricture in a ureter or the urethra, kidney stones, a tumor, or an enlarged prostate. Because of the unrelieved obstruction, urine backs up and distends the ureters and then progresses to the kidney (Fig. 37.3). The capacity of the renal pelvis is normally 5 to 8 mL. Obstruction in the renal pelvis quickly distends it. Kidney pressure increases as the volume of urine increases. This enlargement of the kidney can be either unilateral or bilateral. Unrelieved pressure on the kidneys from urine causes the kidneys to become sacs filled with urine instead of functioning kidneys. Sometimes, in a matter of hours, the blood vessels and renal tubules can be damaged extensively.

If the onset of obstruction is gradual, the patient initially may be asymptomatic. Patients commonly develop UTIs because of the obstruction of urine flow and may have symptoms of frequency, urgency, and dysuria. As the disease progresses, flank and back pain may occur. Eventually the patient develops symptoms of CKD (discussed later).

Treatment of hydronephrosis always involves relieving the obstruction. Initial removal of the obstruction may be done by insertion of an indwelling urinary catheter. Long-term correction depends on the cause and includes treatments and surgeries to relieve obstruction from strictures, stones, tumor or an enlarged prostate. At times, the obstruction cannot be relieved because a stone is too large or removal of tumor growth would result in the patient’s death. In these situations, stents, which are tiny tubes, may be placed inside the ureters during
a cystoscopy and pyelogram (C&P) to hold the ureters open, or a nephrostomy tube may be inserted directly into the kidney pelvis to drain urine. A nephrostomy tube exits through an incision in the flank area and allows urine to drain into a collecting bag so that function of the kidney can be maintained. Figure 37.4 shows a stent in place in a ureter and a nephrostomy tube.

Complications associated with hydronephrosis include increased incidence of UTIs because of obstruction of urine flow and kidney failure from unrelieved pressure on the kidneys. Intake and output are carefully measured. Urine retention can worsen the condition and must be recognized and reported promptly. If the patient has a nephrostomy tube, ensure that it is draining adequately and prevent kinking or clamping of the tube. Kinking of the tube results in continuation of the hydronephrosis, and the resulting pressure will destroy kidney function. If both a nephrostomy tube and urinary catheter are present, output from each should be measured and documented separately.

**TUMORS OF THE RENAL SYSTEM**

**Cancer of the Bladder**

Cancer of the bladder is the most common kind of cancer of the urinary tract. It is most common in men, with the average age being 73. It is more common in Caucasians than in African Americans. The incidence of bladder cancer has been rising in the United States, and the American Cancer Society (ACS) estimates that more than 72,570 new cases of bladder cancer occurred in 2013.

**Pathophysiology**

Cancer of the bladder often starts as a benign growth on the bladder wall that undergoes cancerous changes. Most bladder cancers begin in the inner lining of the bladder called the urothelium. They are called transition cell cancers. They come in a variety of forms and can behave in different ways. Some occur as small wartlike growths on the inside of the bladder. Others form large tumors that grow into the muscle wall of the bladder and require surgical removal. If the cancer affects only the inner lining of the bladder, it is known as a superficial cancer. If it has spread to the muscle wall, it is called an invasive cancer. Common sites for metastasis include the liver, bones, and lungs.

**Etiology**

There is a strong correlation between cigarette smoking and bladder cancer. Those who smoke get bladder cancer twice as often as people who do not smoke. Specific chemicals that cause bladder cancer have been found in cigarette smoke. The more cigarettes smoked, the greater the risk. The lung absorbs the chemicals from tobacco. These chemicals are then passed via the bloodstream to the kidneys and collected in the urine. From there, they accumulate in the urine and damage the cells that line the bladder. Exposure to industrial pollution such as aniline dyes, benzidine and naphthylamine, leather finishings, metal machinery, and petroleum processing products also increases the incidence. It can take about 25 years after exposure to chemicals for bladder cancer to develop. Bladder cancer is often diagnosed at a later stage in women.

**Signs and Symptoms**

Cancer of the bladder usually causes painless hematuria. The patient may notice that the urine is darker or more reddish in color than usual. Blood in the urine is one of the ACS’s seven warning signs of cancer. Initially the bleeding is intermittent,
which often causes the patient to delay seeking treatment. As the disease progresses, the patient develops frank hematuria, bladder irritability, urine retention from clots obstructing the urethra, and fistula formation (an opening between the bladder and an adjoining structure such as the vagina or bowel). Other common signs and symptoms of bladder cancer include pelvic pain, pain in the lower back, painful urination, changes in bladder habits, and inability to void.

**Diagnostic Tests**

Routine urinalysis can detect evidence of bladder cancer. A urine test for the enzyme telomerase has been found to be 90% accurate in detecting bladder cancer in early and late stages. Urine for cytology can be obtained to determine if cancer cells are present in the urine. Urine culture should also be done. Symptoms of bladder infection may be similar to those of bladder cancer. Diagnosis of bladder cancer may also be made with cystoscopy and transurethral biopsy. An IV pyelogram or CT scan also may be done.

**Therapeutic Measures**

Treatment depends on the type and staging (severity) of the bladder cancer. For small, confined tumors, chemotherapeutic agents are instilled into the bladder through a urinary catheter allowed to dwell, and then removed along with the catheter. Systemic chemotherapy is also used and can be helpful to prolong life when other treatments are no longer indicated. The bacille Calmette-Guérin vaccine may be instilled into the bladder to prevent recurring tumors.

Photodynamic therapy, in which drugs are given that make tumors sensitive to light, may be used. When light is applied to the tumor area, cancer cells are killed.

Surgical treatment of bladder cancer includes a number of procedures. A cystoscopy and pyelogram with fulguration (destruction of tissue with electrical current) may be done to burn off cancerous tissue. An alternate method is use of a laser to destroy tumor tissue. Partial cystectomy can be done for cancer limited to one area. Advances in surgical techniques involve robotic and laparoscopic techniques. If the bladder requires removal, robotic laparoscopic radical cystectomy with urinary diversion is an option. In this procedure, robotic surgical equipment, which imitates surgical movements guided by the surgeon, allows more precision, steadiness, and maneuverability than manual surgery, as well as the use of small openings rather than larger incisions into the abdomen. Recovery time is reduced as a result.

**INCONTINENT URINARY DIVERSION.** If the patient has a potentially curable disease with significant bladder involvement, complete removal of the bladder and creation of a urinary diversion may be done. A urinary diversion means that urine leaves the body in a different manner. A common surgery for urinary diversion is called an ileal conduit, an involved surgery in which a 6- to 8-inch section of the ileum or colon is removed and used as a conduit for urine. The remaining portions of the bowel are stitched back together. The surgeon is careful to keep the blood and neurologic supply intact to the section of bowel that has been removed. The isolated section of bowel is closed off on one end, the ureters are stitched into it, and the other end is brought out as a stoma on the abdomen. The urine from an ileal conduit contains mucus because it comes through the ileum, which normally secretes mucus. The patient must wear an ostomy appliance at all times over the stoma to collect urine. Box 37-2 explains how to apply an appliance to an ileal conduit stoma.

**CONTINENT URINARY DIVERSION.** Continent urinary diversion surgeries are being done for patient convenience. One version is the Kock pouch (continent internal ileal reservoir), which is created from a segment of ileum that has been made into a reservoir for urine (see Fig. 37.5B). The ureters are implanted into the side of the reservoir. A special nipple valve is constructed and is the passage way through which the patient inserts a catheter at 4- to 6-hour intervals.
to drain urine. Another version of this surgery is the Indiana pouch (see Fig. 37.5C). A reservoir is created using a portion of the ascending colon and terminal ileum, making a larger pouch than the Kock pouch. Additional versions of this type of surgery use other parts of the bowel and include the Mainz pouch or Florida pouch.

ORTHOTOPIC BLADDER SUBSTITUTION. This surgery involves formation of an orthotopic bladder using a section of the intestine to make a neobladder (neo = new) and implanting both the ureters and the urethra into the neobladder. Various types of orthotopic bladder substitution surgery include the Studer pouch, hemi-Kock pouch, and ileal W-neobladder. After this surgery, the patient can void through the urethra, although incontinence may be a problem and intermittent catheterization may be needed.

Nursing Care

Nursing care of the postoperative patient is similar to care following any major surgical procedure (see Chapter 12). It is important to ensure adequate urinary output and to detect and report any obstruction of urine drainage early to prevent complications. The skin around the stoma will require special care to prevent skin breakdown. The patient is taught how to care for the urinary diversion after surgery, either by frequent draining with a catheter or by wearing an appliance. Be sensitive to the patient’s anxiety about caring for the urinary diversion.
Body image disturbance may occur because of the change in body function. A consultation with a nurse who specializes in wound, ostomy, and continence care (WOC nurse) or an ostomy support group may be helpful both before and after surgery.

**Cancer of the Kidney**

*Pathophysiology and Etiology*

Cancer of the kidney is among the 10 most common cancers in both men and women. The ACS (2013) estimates about 65,150 new cases of kidney cancer will occur in 2013. The lifetime risk of kidney cancer is 1 in 63. Risk factors include genetics, smoking, obesity, hypertension, years of kidney dialysis, and exposure to radiation, asbestos, and industrial pollution. Most patients with kidney cancer are over age 55. It is rare under the age of 45. Men have twice the incidence of women. Often the cancer has metastasized before it is diagnosed because the kidney has such a large volume of circulating blood, which increases the risk of tumor spread. In addition, the disease has few early symptoms.

**Signs and Symptoms**

The three classic symptoms of kidney cancer are hematuria, dull pain in the flank area, and a mass in the area. Often, symptoms of kidney cancer do not occur until the tumor invades surrounding tissue. Less specific symptoms include fever, weight loss, night sweats, hypertension, anemia, polycythemia, swelling in the legs, fatigue, anorexia, and constipation. Symptoms of metastasis may be the first evidence of kidney cancer and include weight loss, cough, bone fractures, liver abnormalities, and increasing weakness.

**Diagnostic Tests**

A number of diagnostic tests will be done, including an IV pyelogram, cystoscopy and pyelogram, ultrasound examination of the kidneys, CT scans of the abdomen, and magnetic resonance imaging (MRI). A definitive diagnosis is made with a renal biopsy.

**Therapeutic Measures**

Surgery is the commonly used treatment for cancer of the kidney. A radical *nephrectomy* removes the entire kidney along with the adrenal gland and other surrounding structures, including fascia, fat, and lymph nodes, in the area. Radiation therapy, immunotherapy, or chemotherapy may be used after the surgery. In nephron-sparing surgery, only the tumor is removed, and the healthy part of the kidney is saved.

**Nursing Care**

After nephrectomy, provide postoperative nursing care for any major surgery (see Chapter 12). Because the kidney is highly vascular, it is essential that the nurse watch for onset of bleeding and any signs of hypovolemic shock. Urine output is monitored. Changes in urine amount or color bleeding, and signs of infection are reported. The patient should be assessed for shortness of breath or diminished breath sounds on the affected side. Surgically induced or spontaneous pneumothorax may occasionally occur after a nephrectomy.

---

**RENAL SYSTEM TRAUMA**

Renal trauma is the most common injury to the urinary system. The kidneys are highly vascular and have a lot of mobility, so they are vulnerable to vascular and tissue damage. The many causes of trauma to the kidney, ureters, and bladder include motor vehicle accidents, sports injuries, falls, gunshot wounds, and stabbing.

Data collection includes a history of the injury and inspection of the abdomen and flank for asymmetry and bruising or swelling of the flank area. Flank pain and hemorrhage may be present. Diagnostic tests include urinalysis, IV pyelogram, ultrasound, CT, and MRI. Treatment depends on the extent of the injury and ranges from bedrest to surgical intervention. Nursing care includes measuring intake and output, monitoring vital signs, and providing IV fluids and pain relief.

Bladder trauma may occur with pelvic fractures and multiple trauma from a blow to the lower abdomen when the bladder is full. The weakest part of the bladder wall, which is the dome located at the top of the bladder, may rupture. Urine leaks out of the peritoneal cavity and around the bowel. The patient can have symptoms of hemorrhage, abdominal pain, inability to void, shock, and pelvic hematoma noted on rectal examination. IV pyelogram and x-ray of the abdomen may be done. A urinary or suprapubic catheter is placed until the bladder heals.

**POLYCYSTIC KIDNEY DISEASE**

Polycystic kidney disease is a hereditary disorder that can result in CKD. The disease affects men and women equally. Polycystic kidney disease is characterized by formation of multiple cysts in the kidney that can eventually replace normal kidney structures. The cysts are grapelike and contain serous fluid, blood, or urine. The patient typically first shows signs of the disease in adulthood. The initial symptoms include a dull heaviness in the flank or lumbar region and hematuria. Other symptoms include hypertension and UTIs. People with inherited polycystic kidney disease may also experience aneurysms in the brain and diverticulosis in the colon. As the disease progresses, the patient develops symptoms of CKD (discussed later). The renal cysts are usually diagnosed with ultrasound imaging. Ultrasound uses no dyes or radiation, so it is safe for all patients, including pregnant women. Often there is a strong family history of polycystic kidney disease.

There is no treatment to stop the progression of polycystic kidney disease. Complications such as UTIs are treated as needed. Headaches that are severe due to hypertension or seem to feel different might be caused by aneurysms in the brain. A patient with severe or recurring headache should see a HCP. As the disease progresses, treatment for hypertension...
and eventual CKD may be needed. Because polycystic disease is hereditary, patients should be counseled about the risks of children inheriting it.

**CHRONIC RENAL DISEASES**

**Diabetic Nephropathy**

Diabetic nephropathy is the most common cause of CKD. It is a long-term complication of diabetes mellitus in which the effects of diabetes result in damage to the small blood vessels in the kidney. Microalbuminuria may be detected within 5 years of the onset of type 1 diabetes and 10 to 15 years after the onset of type 2 diabetes. Renal damage appears about 15 to 20 years after onset of type 1 diabetes, but it may also be a complication of type 2 diabetes. Risk factors for development of diabetic nephropathy include hypertension, genetic predisposition, smoking, and chronic hyperglycemia. Careful control of blood glucose levels reduces the risk of nephropathy in patients with diabetes.

**Pathophysiology**

Multiple factors contribute to diabetic nephropathy. It begins with increased osmotic pressure from hyperglycemia, increased diuresis and compensatory cell growth and expansion, and increased glomerular filtration rate (GFR). Widespread atherosclerotic changes occur in the blood vessels of patients with diabetes, decreasing the blood supply to the kidney. Abnormal thickening of glomerular capillaries damages the glomerulus, allowing protein to leak into urine. Patients with diabetes also commonly develop pyelonephritis and renal scarring. Another complication of diabetes, neurogenic bladder, causes incomplete bladder emptying. This results in urine retention, which can cause infection or obstruction of urine, further damaging the kidneys.

Initially, patients lose only small amounts of protein in their urine (microalbuminuria); this disease can be detected only with careful w atching by the HCP, using frequent examinations of the urine. As the disease progresses, high-output CKD (nonoliguria) can develop, in which a large amount of diluted urine is excreted without the usual amounts of waste products dissolved in the urine. The patient can lose large amounts of protein in the urine and develop nephrotic syndrome, which causes massive edema because of low levels of albumin in the blood. As renal function decreases, the patient needs smaller doses of insulin because the kidney normally degrades insulin. Because the kidney is no longer able to break down insulin and excrete it, small doses of insulin circulate in the body for long periods.

**Symptoms**

The progression of nephropathy is marked by microalbuminuria advancing to proteinuria. Hypertension accelerates the renal damage. As diabetic nephropathy progresses, urine output decreases, toxic wastes accumulate, and the patient develops CKD. For symptoms, see the discussion of CKD in a later section.

**Complications**

Patients with diabetic nephropathy often have a guarded prognosis because they are vulnerable to all the complications of long-term diabetes in addition to kidney disease. The risk of cardiovascular disease is significant with the progression of protein spilling in the urine.

**Diagnostic Tests**

Diabetic nephropathy is diagnosed by carefully watching the patient with diabetes for onset of protein spillage or microalbuminuria in the urine, which is an early sign of the disease. Serum creatinine levels and 24-hour creatinine clearance tests are then done to confirm the presence and extent of diabetic nephropathy.

**Therapeutic Measures**

In the early stages of diabetic nephropathy, strict control of blood glucose levels and blood pressure can help slow the progress of the disease and reduce symptoms. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) may be given to slow the decline of the GFR and microalbuminuria. As the disease progresses, the patient needs dialysis to maintain life. Unfortunately, other complications related to diabetes cause patients to tolerate dialysis less well than patients with CKD from other causes. Kidney or kidney-pancreas transplant, when available, is the treatment of choice for the patient with diabetic nephropathy and often improves the patient’s chance for a healthier life.

**Nephrotic Syndrome**

Nephrotic syndrome is the excretion of 3.5 g or more of protein in the urine per day. Nephrotic syndrome may occur as a result of other disease processes. In nephrotic syndrome, large amounts of protein are lost in the urine from increased glomerular membrane permeability. As a result, serum albumin and total serum protein are decreased. Normally, albumin and other serum proteins maintain fluid within the vascular space. When levels of these proteins are low, fluid leaks from the blood vessels into tissues, resulting in edema. With very low levels of protein, ascites and massive widespread edema (anasarca) occur. In response to the low protein levels, the liver produces lipoproteins. As a result, serum cholesterol, low-density lipoproteins, and triglyceride levels are elevated. Urine may appear foamy from lipoproteinemia. Loss of immunoglobulins may lead to increased susceptibility to infection. Elevated blood pressure readings are noted.

Treatment is focused on the cause and symptoms of nephrotic syndrome. To control edema, sodium intake is restricted. Protein intake is based on the severity of urinary protein loss. Diuretics may be used. Lipid-lowering drugs may be tried. Anticoagulants are given for thrombosis prevention. In some cases, corticosteroids may be used to reduce inflammation.

Complications of nephrotic syndrome include impaired immune function, nutritional imbalances, and, most importantly, 

**WORD BUILDING**

*nephropathy*: nephro—pertaining to the kidney + pathy—disease
Nephrosclerosis

Hypertension damages the kidneys by causing sclerotic changes in the small arteries and arterioles, such as arteriosclerosis with thickening and hardening of the renal blood vessels (nephrosclerosis). Arteriosclerotic changes in the kidney blood vessels result in a decreased blood supply to the kidney (ischemia of the kidney) and can eventually destroy the kidney. The remaining nephrons try to compensate with vasodilation to increase blood flow to the glomeruli. This results in increased glomerular pressure and filtration, which thickens the blood vessels. High pressure in the kidneys causes the vessels to weaken and hemorrhage. Large areas of the kidney become damaged. Symptoms of nephrosclerosis include proteinuria, hyaline casts in the urine, and, as it progresses, symptoms of CKD.

The treatment for nephrosclerosis is to reduce blood pressure and treat the hypertension. The patient is placed on antihypertensive medications or, if already on these, changed to stronger antihypertensive medications. The patient is placed on a low-sodium diet. Dialysis may be used to maintain life. The prognosis is often poor because by the time the patient has developed nephrosclerosis, there is widespread arteriosclerosis throughout the body. Arteriosclerosis makes the patient prone to myocardial infarctions or cerebrovascular accidents.

The major nursing diagnosis that is relevant when the patient develops nephrosclerosis is Ineffective Health Maintenance. The priority is to help the patient learn as much about the control of hypertension as possible. The patient should also be taught the symptoms of CKD. Once the patient has lost renal function, the nursing care plan for CKD is appropriate.

CRITICAL THINKING

Mr. Stevens

Mr. Stevens is a 35-year-old African American man admitted to the intensive care unit with uncontrolled hypertension. His blood pressure is controlled by IV medication. His laboratory tests show protein and hyaline casts in the urine. He is diagnosed with nephrosclerosis.

1. What data should the nurse collect as part of the morning evaluation of the patient’s condition?
2. What other renal function tests are appropriate for the nurse to check?
3. What teaching does Mr. Stevens need when his condition is more stable?

Suggested answers are at the end of the chapter.
Edema may begin around the eyes (periorbital edema) and face and progress to the abdomen (ascites), lungs (pleural effusion), and extremities. Flank pain may be present. Blood urea nitrogen (BUN) and creatinine levels may be elevated. Urinalysis shows RBCs, WBCs, albumin, and casts. The urine is dark or cola colored from old RBCs and may be foamy because of proteinuria.

**Complications**

The prognosis is good for acute glomerulonephritis acquired in childhood, and most children recover completely. Adults who develop glomerulonephritis may recover renal function or progress to chronic glomerulonephritis. Some patients develop rapidly progressive glomerulonephritis, which can quickly lead to acute renal injury. Chronic glomerulonephritis is a slow process characterized by hypertension, gradual loss of renal function, and eventual CKD.

**Diagnostic Tests**

Glomerulonephritis is diagnosed with urinalysis, which shows protein, casts, or RBCs and elevated serum levels of nitrogenous wastes (creatinine, urea). Hypertension may be present. Kidney ultrasound, x-ray, or biopsy may be done to determine abnormal kidney shape, size, blood flow, inflammation, or scarring of the glomeruli.

**Therapeutic Measures**

Most cases of acute glomerulonephritis resolve spontaneously in about a week, but some progress to CKD. Treatment is primarily symptomatic. Sodium and fluid restrictions may be ordered, along with diuretics to treat fluid retention. Medications may be given to control hypertension. If associated with a streptococcal infection, antibiotics are given to treat any remaining infection. If fluid overload is severe, dialysis may be done.

**Nursing Care**

Nursing care for a patient with glomerulonephritis focuses on symptom relief. Vital signs are monitored because the patient may be critically ill. During the acute phase, rest is encouraged. Edema is controlled with fluid and sodium intake restrictions. Protein intake may be limited if the kidneys are not filtering protein waste products (as seen by increased serum BUN and creatinine levels). Other care is discussed in the next section on CKD. Teaching the patient about preventing glomerulonephritis is important. Antibiotics for diagnosed streptococcal throat infections should be taken for prevention.

### ACUTE KIDNEY INJURY OR CHRONIC KIDNEY DISEASE

Kidney disease is diagnosed when the kidneys are no longer functioning adequately to maintain normal body processes. This results in dysfunction in almost all other parts of the body as a result of imbalances in fluid, electrolytes, and calcium levels, as well as impaired RBC formation and decreased elimination of waste products. It can be acute (acute kidney injury) with sudden onset of symptoms, or it can be chronic (CKD), occurring gradually over time. For more information on kidneys, visit the American Kidney Fund (www.kidneyfund.org), the National Kidney Foundation (www.kidney.org), and the American Association of Kidney Patients (www.aakp.org).

### Acute Kidney Injury

Acute kidney injury (AKI) is the sudden (hours to days) loss of the kidneys’ ability to clear waste products and regulate fluid and electrolyte balance. Rapid accumulation of toxic wastes from protein metabolism in the blood (azotemia) occurs. In azotemia, the serum urea level (measured by BUN) and creatinine level are elevated. Potassium imbalances may lead to tachycardia. Most types of AKI are reversible if diagnosed and treated early; however, AKI can lead to CKD. It is often associated with a urine output of less than 30 mL/hr or 400 mL/day. It may be caused by hypotension, dehydration, vascular obstruction, glomerular disease, or acute tubular necrosis, in which the tubules are damaged. This may occur after administration of diagnostic contrast agents (contrast-induced nephropathy).

**WORD BUILDING**

azotemia: azo—nitrogenous waste products + temia—blood
In the oliguric phase, fluid is retained, electrolytes become imbalanced, and waste products are not excreted as urine output decreases. Signs of fluid overload arise. Serum potassium rises while sodium is lost in the urine, creating a normal or low serum sodium level. The longer this phase lasts, the more effects that are seen. These may include metabolic acidosis from reduced hydrogen ion excretion and sodium bicarbonate levels, increased phosphate and decreased calcium levels, abnormal blood cells (RBCs, WBCs, platelets), neurologic effects ranging from confusion to seizures to coma, and finally effects on all body systems as is seen in chronic renal failure (discussed later).

**Diuretic Phase.** As the kidneys begin to excrete waste products again, 1 to 3 L/day of urine is produced. Osmotic diuresis occurs from the elevated waste products (urea), which the body is attempting to eliminate. The kidneys are not yet able to concentrate urine, so dehydration and hypotension are a concern. It is important for the nurse to monitor for hypovolemia, hypotension, hypokalemia, and hypotension in this phase. Serum BUN and creatinine levels are high until the end of this phase, when they begin to return to normal. This phase may last 1 to 3 weeks.

**Recovery Phase.** In this final phase, recovery begins as the glomerular filtration rate rises. Waste product levels (BUN, creatinine) decrease greatly within the first 2 weeks of this phase. However, recovery can take up to 1 year. Those who do recover usually do so without complications. Older adults are more at risk for reduced recovery of renal function. In those who do not recover renal function, CKD occurs.

**Etiology**

AKI is often classified as prerenal, intrarenal, or postrenal. These categories relate to the causes leading to the injury. Each category is associated with the location of the cause in the kidney. Understanding the cause can point to the direction of treatment plans helpful to the patient.

**Prerenal Injury.** Prerenal (before the kidney) injury, the most common cause of AKI, is associated with a decrease or interruption of blood supply to the kidneys. Causes may include decreased blood pressure from dehydration, blood loss, shock, or trauma to or blockage in the arteries that carry blood to the kidneys. When the nephrons receive an inadequate blood supply, they are unable to make urine, and waste products are not adequately removed. Use of nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX) inhibitors can also lead to prerenal injury. These drugs impair the autoregulatory responses of the kidneys by blocking prostaglandin, which is needed for renal perfusion.

Prerenal injury can be diagnosed by evaluating possible causes. If dehydration is the cause, then an IV fluid challenge may be given. With increased IV fluid, more blood flows to the kidneys for filtering, which increases urine output and waste product filtering. An arteriogram of the renal arteries is helpful to determine if the blood supply to the kidneys is decreased or blocked; angioplasty may be used to open the blockage. Serum creatinine increases and creatinine clearance

---

**Pathophysiology**

There are three major mechanisms of injury in AKI. These mechanisms are hypoperfusion, direct tissue injury, and hypersensitivity reactions causing renal inflammation. In AKI, rapid damage to the kidney causes waste products to accumulate in the bloodstream, resulting in signs and symptoms. The patient becomes oliguric, with urine output decreasing to less than 20 mL/h. Treatment is directed toward correcting the cause, supporting the patient with dialysis, and preventing complications that may lead to permanent damage. Many patients with AKI recover completely. About 40% to 50% of patients hospitalized with intrarenal AKI die from complications, such as infection, pneumonia, or sepsis (Pannu et al, 2011).

AKI can progress through four stages, with an intrarenal cause taking a longer recov very time because there is actual renal damage. Once an event causes AKI in the initial phase, symptoms occur in hours to days.

**Oliguric Phase.** In the oliguric phase, less than 400 mL of urine is produced in 24 hours. Fifty percent of those with AKI experience this phase, which occurs from 24 hours to 7 days after the initial phase. This phase can last up to 2 weeks to several months. Prognosis for renal recovery is decreased the longer this phase lasts.
decreases. Urinalysis may be helpful in determining the cause as well.

Newer biomarkers such as interleukin 18, neutrophil gelatinase–associated lipocalin (NGAL), and kidney injury molecule-1 (KIM-1) might be able to provide more information on the type of kidney injury. These markers are under ongoing study.

**INTRARENAL INJURY.** Intrarenal (inside the kidney) injury occurs when there is damage to the nephrons inside the kidney. The most common causes are ischemia, reduced blood flow, and toxins. Other causes are infectious processes leading to glomerulonephritis, trauma to the kidney, exposure to nephrotoxins, allergic reactions to contrast agents, and severe muscle injury, which releases substances that are harmful to the kidneys.

A number of substances can be toxic to the kidneys (nephrotoxic) when they enter the body (Table 37.7). Kidney damage is most likely to occur when these substances enter the body in high concentrations or when preexisting kidney damage is present for some other reason. Many commonly administered medications can be nephrotoxic. Aminoglycosides are nephrotoxic antibiotics; when they are administered, blood levels of the drugs are carefully monitored to avoid toxic levels.

**CONTRAST-INDUCED NEPHROPATHY.** Contrast agents used during tests such as IV pyelograms and CT scans can cause kidney damage, especially when the patient is dehydrated and has preexisting renal damage. The incidence increases with age greater than 60 years, decreased renal function, poor renal perfusion, or exposure to nephrotoxic drugs. Contrast media has the potential to cause renal vasoconstriction, hypoxia, and alteration of renal blood flow (Jorgensen, 2013). Loss of regulation of renal blood flow causes decreased oxygen transport with causes increasing renal medullary hypoxia, necrosis and renal cell tubular collapse (Isaac, 2012). Before administration of contrast media, patients should be assessed for risk factors: diabetes mellitus, hypertension, dyslipidemia, advanced age over 70, renal surgery. Anemia, proteinuria, hyperuricemia, and the use of diuretics and other nephrotoxic drugs increases the likelihood of contrast-induced nephropathy. Prevention strategies should focus on screening patients for dehydration and risk factors. IV hydration with normal saline is most effective. Hydration is inexpensive and usually without risks. Studies are being done on the use of sodium bicarbonate infusion as well as the use of N-acetylcysteine to prevent contrast-induced nephropathy. (Jorgensen, 2013).

**POSTRENAL INJURY.** Postrenal (after the kidney) injury is associated with an obstruction that blocks the flow of urine out of the body. Only 5% of acute kidney injuries are classified as postrenal. In this case, the blood supply to the kidneys and nephron function initially may be normal, but urine is unable to drain out of the kidney, resulting in the buildup of urine and impaired nephron function. Common causes are kidney stones, tumors of the ureters or bladder, and an enlarged prostate that blocks the flow of urine.

Diagnosis of causes can be done with x-ray examination of the kidneys, ureters, and bladder. Cystoscopy will show tumors, stones, or prostate enlargement. Renal ultrasound can measure kidney size, detect tumors and blockages, and reveal cystic disease. Surgical intervention may be needed to correct the problem.

**Measures**
AKI is treated by relieving the cause. Prevention of permanent damage is the goal of treatment. Signs and symptoms are managed as they develop, and supportive care is given. Treatment may include restoring fluid and electrolyte balance, discontinuing nephrotoxic drugs that may have caused the problem, bypassing urinary tract obstructions with catheters, or using short-term continuous renal replacement therapy.

therapy to filter blood and restore potassium and other electrolytes to normal. Some symptoms, such as anemia, may not have time to develop in the patient with AKI as they do in CKD. The care of the patient with AKI is similar to care of the patient with CKD.

**CONTINUOUS RENAL REPLACEMENT THERAPY.** Continuous renal replacement therapy (CRRT) is used to remove fluid and solutes in a controlled, continuous manner in unstable patients with AKI. Unstable patients may not be able to tolerate the rapid fluid shifts that occur in hemodialysis, so CRRT provides an alternative therapy that results in less dramatic fluid shifting. CRRT can be used with hemodialysis, which is needed if severe symptoms of uremia (hyperkalemia) are present. CRRT is not as complex as hemodialysis and can be done for more than a month, if needed, via temporary vascular access.

During CRRT, a permeable hemofilter is attached to the vascular access. Blood flows through the hemofilter and excess fluids and solutes move into a collection bag. The remaining blood returns to the patient via the venous access. If desired, replacement fluid and electrolytes can be given through the vascular access. Monitoring intake and output, fluid and electrolytes, daily weights, hourly vital signs, and vascular access is important.

**Chronic Kidney Disease**

Kidney disease is the eighth leading cause of death in the United States (U.S. Renal Data System, 2013), where CKD affects about 26 million people and the incidence is on the rise. This disease is a progressive, irreversible deterioration in renal function in which the body is unable to maintain metabolic, fluid, and electrolyte balance. It occurs with a gradual decrease in the function of the kidneys over time. The result is accumulation of nitrogenous waste products in the blood and uremia. CKD affects every body system (Table 37.8).

**Pathophysiology**

When a large proportion of the body’s nephrons are damaged or destroyed, AKI or CKD occurs. As the nephrons die off, the undamaged ones increase their work capacity and take over the work previously done by the dead ones, so the patient may experience significant kidney damage without showing symptoms.

CKD is a progressive disease process. In the early, or silent, stage (decreased renal reserve), the patient is usually without symptoms, even though up to 50% of nephron function may have been lost (Table 37.9). This stage is often not diagnosed.

The renal insufficiency stage occurs when the patient has lost 75% of nephron function and some signs of mild kidney disease are present. Anemia and the inability to concentrate

**WORD BUILDING**

**Hemodialysis:** hemo—blood + dialysis—passage of a solute through a membrane

**Uremia:** ur—urea + emia—in the blood
urine may occur. BUN and creatinine levels are slightly elevated. These patients are at risk for further damage caused by infection, dehydration, drugs, heart failure, and use of diagnostic x-ray dyes. The goal of care is to prevent further damage, if possible, by control of blood glucose levels and blood pressure.

End-stage renal disease occurs when 90% of the nephrons are lost. Patients at this stage experience chronic and persistent abnormal kidney function. BUN and creatinine levels are always elevated. These patients may make urine but not filter out the waste products, or urine production may cease. Dialysis or a kidney transplant is required to survive.

Uremia (urea in the blood) is present in CKD. Patients eventually develop problems in all body systems (Table 37.10). If left untreated, the patient with uremia dies, often within weeks.

Etiology
The causes of CKD are numerous. The most common include diabetes mellitus resulting in diabetic nephropathy, chronic high blood pressure causing nephrosclerosis, glomerulonephritis, and autoimmune diseases. Diabetes and hypertension account for close to 70% of all CKD (U.S. Renal Data System, 2013).

Symptoms of Kidney Disease
Patients in either AKI or CKD have multiple symptoms. Figure 37.6 illustrates symptoms and some of the more common ones are explained next.

Disturbance in Water Balance
Disturbances in the removal and regulation of water balance in the body occur with signs of fluid accumulation. An early symptom is edema (swelling) of the extremities, sacral area, and abdomen. Patients may report shortness of breath. Crackles and wheezes (signs of fluid accumulation) may be present on auscultation of the lungs. Blood vessels in the neck may be distended, and the patient may be hypertensive. These patients may produce a large amount of dilute urine (polyuria), small amounts of urine (oliguria), or no urine (anuria).

Disturbance in Electrolyte Balance
As kidney function decreases, the kidneys lose their ability to absorb and excrete electrolytes. Important electrolytes are sodium, potassium, and magnesium. When the kidneys are unable to maintain normal amounts of electrolytes in the blood, these substances accumulate at high levels and may be life threatening.

When the kidneys are unable to regulate sodium levels adequately, the patient may show signs of hyponatremia (excessive sodium in the blood), which causes water retention, edema, and hypertension. Hyponatremia (too little sodium) may occur when too much sodium is lost. This occurs when the patient has experienced prolonged episodes of vomiting or diarrhea or is urinating large amounts of diluted urine. Patients with hyponatremia may show signs of confusion. The sodium may be normal or low due to being diluted from excess fluid.

Hyperkalemia (potassium level exceeding 5 mEq/L) can be life threatening if the level goes above 7 mEq/L. The patient may have dysrhythmias and cardiac arrest if the potassium level is too high. Patients with hyperkalemia report muscle weakness, abdominal cramping, and diarrhea. The nurse may identify that the patient is confused or disinterested in care. These patients should be placed on a cardiac monitor and observed for cardiac dysrhythmias.

A high potassium level in the patient with CKD may be caused by a diet high in potassium-rich foods, injuries, or blood transfusions. Monitoring daily laboratory values, restricting potassium intake, and reporting abnormalities are important. IV insulin with glucose, or calcium gluconate may be used as a temporary measure to drive excess potassium into the cells. Sodium polystyrene sulfonate (Kayexalate) may be given either orally or as a retention enema; it causes potassium to be eliminated through the stool. The definitive treatment for hyperkalemia is hemodialysis, which removes potassium from the body. Dietary education is extremely important. The patient is instructed to avoid foods that are high in potassium (Box 37-3).

Calcium levels decrease because the kidneys are unable to produce the hormone that activates vitamin D, the vitamin needed for calcium absorption. Hypocalcemia exists when the calcium level falls below 8.5 mg/dL. Also associated with a low calcium level is hyperphosphatemia, a phosphorus level above 5 mg/dL. These imbalances cause the bones to release

- Juice: carrot, prune, tomato, vegetable
- Nuts
- Vegetables: beet greens, potatoes (chips, sweet, white, yams), spinach, squash
- Salt substitutes
- Seeds
calcium, increasing the risk of fractures. These patients should ambulate regularly to prevent further calcium loss from the bone. Many patients who are on dialysis develop hypercalcemia due to hyperparathyroidism (excess release of parathyroid hormone). Cinacalcet (Sensipar) reduces excess levels of parathyroid hormone, which then reduces calcium levels.

Phosphates are also found in many foods. Medication to bind phosphate, known as phosphate binders, is taken by patients with high phosphate levels. Patients must take these medications with meals so they can bind with the phosphates and be eliminated in the stool. High phosphorus levels may cause severe itching, and patients may have open sores from scratching, placing them at risk for infections. Patients also may have muscle cramps and aches.

**Disturbance of Removal of Waste Products**

With azotemia (rapid accumulation of toxic wastes in the blood), the patient may show signs of weakness and fatigue, confusion, seizures, twitching movements of extremities (asterixis), nausea, vomiting, and lack of appetite and may report a metallic or bad taste in the mouth. There may be a smell of urine on the patient’s breath. The patient may have yellowish pale skin and report itching due to urea crystals on the skin. Dialysis to remove excessive waste products in the blood is the only treatment for the underlying causes of these symptoms.

**Disturbance in Maintaining Acid–Base Balance**

Hydrogen ion excretion is affected, causing a disturbance in the acid–base balance that result in metabolic acidosis. Patients may report headache, fatigue, weakness, nausea, vomiting, and lack of appetite. As metabolic acidosis progresses, the patient shows signs of lethargy, stupor, and coma. Respirations become fast and deep as the lungs attempt to blow off carbon dioxide to correct the acidosis (Kussmaul’s respirations). See Chapter 6 for a more detailed discussion of acid–base balance.

**Disturbance in Hematologic Function**

Anemia is seen mainly in CKD, which causes disturbances in blood cells over time. Damaged kidneys do not produce adequate erythropoietin, the hormone that stimulates RBC production. Nutritional deficiencies and blood loss during dialysis also contribute to anemia. Regular injections of epoetin (EpoGen, Procrit), a synthetic form of erythropoietin, help restore RBC production and prevent anemia. A common side effect of erythropoietin is development of hypertension.

Impaired WBC and immune functions contribute to an increased risk for infection. The patient should be protected from potential sources of infection.

Impaired platelet function creates a risk for bleeding. The patient should be protected from injury, and signs of bleeding, such as blood in stool or emesis, are reported.

**Therapeutic Measures for Kidney Disease**

Kidney insufficiency and early kidney disease are treated based on symptoms with a restricted diet and fluid intake, medications, and careful monitoring for onset of serious problems that warrant initiation of dialysis. In later stages, dialysis is necessary to replace lost kidney function. A kidney transplant, when available, may return the patient to a nearly normal state of health.

**Diet**

Dietary recommendations are individualized by the dietitian and HCP based on the patient’s needs. Calories are high to maintain weight and energy needs. Protein is usually restricted to limit nitrogen intake but is increased for a patient on dialysis because protein is lost during the dialysis process. Sodium is restricted to minimize sodium and fluid retention. Potassium is restricted, especially later in the disease when the kidneys are unable to eliminate it. Calcium may be increased or supplemented because of poor absorption related to faulty vitamin D activation. Phosphorus is restricted because of high blood levels related to hypocalcemia. Saturated fat and cholesterol are restricted for patients with hyperlipidemia. Fluids are restricted to prevent overload. Most patients are given iron, folic acid, vitamins, and minerals to supplement the restricted diet (“Nutrition Notes”).

Because restrictions are complex, the diet may be a source of frustration for patients. The nurse should assist the patient to identify foods that are palatable yet within the diet plan. The dietitian should be consulted for instruction and assistance.

**Medications**

Early in the disease, diuretics are given to increase output, and ACE inhibitors, angiotensin receptor blockers, calcium channel blockers, or beta blockers may be used to control hypertension. Phosphate binders are given with meals to reduce phosphate levels. Calcium and vitamin D supplements are used to raise calcium levels. Both the active and storage forms of vitamin D should be considered to decrease fractures, cancer, and infection rates and improve cardiac function. Agents to lower potassium levels are used if needed. All drug therapy is closely monitored because diseased kidneys are unable to effectively remove medications from the body. The patient with diabetes needs less insulin because one of the functions of the kidneys is to break down insulin. Because it is not being broken down, it remains in the body longer, and therefore less is needed as the kidney disease progresses.

**Dialysis**

Dialysis is started when the patient develops symptoms of severe fluid overload, high potassium levels, acidosis, pericarditis, vomiting, lethargy, fatigue, or symptoms of uremia that are life threatening. Both peritoneal dialysis and hemodialysis involve the movement and diffusion of particles from an area of high concentration to an area of low concentration through a semipermeable membrane. Substances move from blood through the semipermeable membrane into the dialysate. Fluid and electrolyte imbalances can be corrected with dialysis. Dialysis can also be used to treat drug overdoses.

**HEMODIALYSIS.** Hemodialysis involves the use of an artificial kidney to remove waste products and excess water from the...
During the dialysis procedure, the patient’s blood and the dialyzing solution flow in opposite directions through the dialyzer across an enclosed semipermeable membrane. The dialysate contains electrolytes and water in a balanced mix that resembles blood plasma. On the other side is the patient’s blood with metabolic waste products, excess water, and electrolytes. The waste products from the patient’s blood move into the dialysate by diffusion through the membrane because of the difference in their concentrations. The dialysate solution carries the waste products away, and the cleansed blood is returned to the patient’s body through another tube (Fig. 37.7). A hemodialysis treatment takes 3 to 4 hours and is usually done three or four times a week. Hemodialysis can be done at a hemodialysis center, at home, or in the hospital if the patient develops a complication and needs hospitalization (Fig. 37.8).

Hemodialysis provides a rapid and efficient way to remove waste products from the blood. It is also an excellent means to correct excessive fluid-overloaded states such as occur in heart failure.

Hemodialysis is not without side effects. After a treatment, the patient normally feels weak and fatigued, sometimes even too tired to eat. Sudden drops in blood pressure may cause the patient to become weak, dizzy, and nauseated. Cardiac dysrhythmias and angina may occur. Fluid and electrolyte levels drop rapidly and cause the patient to become weak and fatigued.

Nutrition Notes
Understanding Dietary Changes in Renal Disease

Patients with impaired renal function require careful coordination of diet with current physiological status, which may change frequently, necessitating the services of a diettitian who specializes in renal treatment. The following principles are offered as general guidelines:

- Maintaining caloric intake is essential to avoid catabolism of tissue for energy. Simple carbohydrates and monounsaturated and polyunsaturated fats are given freely because their end products, carbon dioxide and water, are less likely than protein to tax the kidney. Patients with diabetes and uremia may receive more sugar than usual because treatment of the uremia may take precedence over the diabetes; however, patients with type IV hypertriglyceridemia may have to limit carbohydrates.

- Protein may be restricted when the patient’s kidneys are failing but increased when the patient is treated with dialysis to compensate for losses in the dialysate. Sometimes proteins of high biological value (e.g., eggs, meat, and dairy products) are prescribed because they are more easily converted to body protein than those of low biological value. In other situations, vegetarian diets may be given, with the plant proteins carefully selected to manage potassium and phosphorus serum levels.

- Sodium may be restricted, depending on blood pressure, edema, and laboratory findings.

- Potassium may be restricted for patients with oliguria. Salt substitutes are often potassium compounds that are to be avoided. Potassium content in foods varies with processing and preparation methods, so patients should choose from prescribed foods only.

- Fluid restriction may be altered daily according to output. Patients with renal insufficiency may receive 500 mL plus the amount of the previous day’s output.

In short, renal diets are individualized for the patient’s current condition. Nurses should not expect various patients to be served the same meals or even the same patient to require the same restrictions from one day to the next. Counseling and teaching patients to associate adherence to the diet and relief of symptoms is an important nursing task that encourages patients to persevere in managing their situation.

*Nepro (Abbott Laboratories) is a specially formulated oral supplement to meet the altered nutrition needs of patients on dialysis. Nepro blends carbohydrates to maintain steady glucose levels and increase albumin levels.

feel lethargic and have muscle cramps. Patients are given large amounts of heparin, an anticoagulant, to keep the blood from clotting while it is in the artificial kidney; this may cause bleeding from the puncture sites, GI tract, nose, or other sites if injury occurs. Box 37-4 reviews nursing care for patients having hemodialysis.

**Vascular Access.** Hemodialysis requires a permanent way to access the bloodstream for blood removal and return to the body during dialysis. Typical permanent vascular access options are an arteriovenous (AV) fistula (considered to be the gold standard) or a vascular access graft. Fistulas or grafts are placed in the arm when possible.

---

**NURSING CARE TIP**

It is important to save the veins of patients with CKD for possible future fistula creation. The non-dominant patient arm should not be used for IVs, blood draws, or blood pressure to avoid damage to the veins because it will likely be the arm used for the fistula. Early consultation with a nephrologist can identify which veins to protect.

---

**Box 37-4  Care for Hemodialysis**

1. Consult with the HCP about medications to hold before hemodialysis. Some medications, such as antihypertensives, can be harmful when they become effective during dialysis and can reduce blood pressure to dangerously low levels. Other medications are water-soluble and will be dialyzed out of the body, and thus are not effective.

2. Ensure that the patient is weighed both before dialysis in the morning and after dialysis to document weight loss as a result of fluid removal.

3. If the patient has laboratory tests ordered and blood needs to be drawn, coordinate this process with the dialysis nurse, who can obtain the blood samples and save the patient unnecessary needlesticks.

4. Try to get morning care done early and breakfast given before dialysis, if the patient tolerates eating before dialysis. In some patients, eating can cause hypotension by diverting blood flow to the gastrointestinal system for digestion during dialysis. After dialysis, patients are often exhausted and need rest.

5. When the patient returns from dialysis, weigh the patient, assess the access site for bleeding, and make sure the vital signs are stable. Administer medications that were held if not contraindicated and vital signs are stable.

6. Protect the patient’s dialysis access as outlined in Box 37-5, *Care of Blood Access Fistula or Graft*.

---

Early referral to a nephrologist can allow for the establishment of vascular access so that it is matured (developed) before the need for dialysis. If this does not occur, then a temporary access is used until a fistula or graft is placed or usable. A central venous catheter with two or three ports (the third port can be used for medications by trained staff) is placed in a central vein for temporary access. Central catheters should not be used long term because of the risk of infection.

An AV fistula is made by sewing a vein and artery together under the skin (Fig. 37.9). AV fistulas may take several weeks to mature. The surgeon determines when the fistula is mature for use.

An AV graft uses a tube of synthetic material to attach to an artery and a vein. Needles are inserted into the graft to access the patient’s blood. Traditional graft material is not self-sealing and requires time for tissue growth to serve as a plug for the hole that the needle makes before it can be used. This may take 1 to 2 weeks. The Vectra® vascular access graft is self-sealing and does not require tissue growth so it can be used almost immediately after surgical implantation. This self-sealing property also decreases postdialysis bleeding time and reduces the time required for the dialysis session.

**Vascular Access Care.** AV fistulas and grafts are regularly checked for patency by palpating for a thrill (a tremor) and auscultating for a bruit (swishing sound) at the site of the graft or fistula. Any decrease or cessation of bruit or thrill indicates occlusion. If a thrill or bruit is diminished or not present, the HCP is notified immediately. Special care of the access site must be taken because this is the patient’s only way to eliminate waste products (Box 37-5). It is important for the site to be carefully monitored per institution policy to detect any clotting or problems. Early detection of clotting allows the
Postoperative Care. Initially, neurovascular checks are performed hourly for vascular surgery. Neurovascular checks include extremity movement and sensation, presence of numbness or tingling, pulses, temperature, color, and capillary refill (normally less than 3 seconds). Peripheral pulses are palpated to feel the thrill and auscultated to hear the bruit. If a pulse is absent or weak or the extremity is cool or dusky, the HCP is notified immediately. Dressings or incisions are checked, and any drainage, hematoma, or infection is documented and reported as needed. Vascular surgery pain is usually mild. Severe pain may indicate an occlusion of the graft. AV grafts can cause distal ischemia or “steal syndrome” because too much of the arterial blood is being “stolen” from the distal extremity. This is usually seen postoperatively and may require surgical correction to restore blood flow to the extremity.

Blood pressure readings and IVs should not be done in the extremity in which the access is placed. The extremity with the vascular access should be elevated postoperatively. Range-of-motion exercises should be encouraged. Patients are taught care of the access (see Box 37-5).

**Box 37-5 Care of Blood Access Fistula or Graft**

These dialysis access sites should not be used for any purpose other than dialysis.

1. Watch for signs of bleeding or infection at the site.
2. Listen for a bruit at the site by placing the diaphragm of a stethoscope gently on the site. A bruit is a swirling sound made as the blood passes through the access site.
3. Gently palpate the site for a thrill, which is a buzzing or pulsing feeling that indicates good blood flow through the access site.
4. Do not take blood pressure, use a tourniquet, draw blood, or start any IV lines in the affected arm. Injections should be avoided if possible.
5. Many hospitals have the patient wear a red arm bracelet to signify that the arm should be protected. A sign above the bed may also be used.
6. Teach the patient to keep the site clean and not to bump or cut it.
7. Teach the patient to follow weight restrictions for lifting with the access arm.
8. Teach the patient to avoid wearing constrictive clothing or jewelry over the site.
9. Teach the patient to avoid prolonged bending or sleeping on the arm with an access.
10. Notify the HCP if signs of bleeding, reduced circulation, or infection occur in the access extremity: coldness, numbness, weakness, redness, fever, drainage, or swelling.

PERITONEAL DIALYSIS. Peritoneal dialysis provides continuous dialysis treatment and is done by the patient or family in the home. The peritoneal membrane is used as a semipermeable membrane across which excess wastes and fluids move from blood in peritoneal vessels into a dialysate solution that has been instilled into the peritoneal cavity. A peritoneal catheter is placed into the patient’s peritoneal space between the two layers of the peritoneum below the waistline. This catheter is used to perform an exchange. The exchange process has three steps: (1) filling, (2) dwell time, and (3) draining.

The fill step involves instilling a bag of sterile dialyzing solution (dialysate) into the patient’s peritoneal cavity through the catheter. The amount of solution is individualized but is often 1000 mL. The solution is left to dwell in the abdomen for several hours, allowing time for the waste products from the blood to pass through the peritoneal membrane into the dialysate solution (Fig. 37.10).

The solution is then drained out of the body and discarded. This process is repeated three or four times a day and is continuous for the patient. Several treatment plans use this exchange process. The treatment plan that best suits the patient’s needs is determined by the patient and the dialysis team.

Continuous ambulatory peritoneal dialysis is the most commonly used treatment plan. Usually three exchanges are done during the day and one before bedtime. Other treatment plans allow for the use of a computerized machine called a cycler to regulate the exchanges during sleeping hours. Sometimes medications are added to the dialyzing solutions, such as heparin to prevent clotting of the catheter, insulin for the patient with diabetes, or antibiotics if there is infection.

Patient and family education is extremely important for peritoneal dialysis to be successful. The patient must be taught and be able to demonstrate that he or she is able to do a successful exchange. Sterile technique while performing the exchanges is imperative, and the exchanges should be done in a clean environment. A major complication is peritonitis (infection of the peritoneum), which can be life-threatening. The major cause of peritonitis is poor technique when connecting the bag of dialyzing solution to the peritoneal catheter. The first sign of peritonitis is usually abdominal pain. (See Chapter 34 for additional signs and symptoms of peritonitis.) If any symptoms of peritonitis occur, the patient must contact the HCP immediately so antibiotic treatment can begin. The patient should be taught to care for the exit site (the site where the catheter comes out of the abdomen) and the need to inspect both the site and the dialysate solution for any signs of infection.

Dietary education is also important. A dietitian can assist the patient in making appropriate choices for adequate calories, protein, and potassium intake. The peritoneal dialysis patient typically has fewer dietary and fluid restrictions than the patient on hemodialysis because peritoneal dialysis is...
continuous and maintains serum waste levels. Proteins are lost through the peritoneal membrane into the dialysate fluid, so increased dietary protein is needed. This loss increases with peritonitis, which further increases permeability.

**LEARNING TIP**

Differences among hemodialysis (HD), peritoneal dialysis (PD), and continuous renal replacement therapy (CRRT) include the following:

- **Patient access:** HD requires vascular access. PD requires insertion of a catheter into the peritoneal cavity. CRRT requires temporary vascular access such as a central line.
- **Equipment:** HD requires a specialized complex dialyzer. PD and CRRT do not require the specialized dialyzer, although machines are available for these therapies.
- **Training:** HD requires a skilled HD nurse. CRRT can be done by a non-HD nurse in a critical care setting. PD can be done by the patient.
- **Timing:** HD is intermittent. PD and CRRT are continuous.
- **Solute removal:** HD and PD use the principles of osmosis and diffusion, which require a dialysate solution. CRRT uses convection, so no dialysate is needed.
- **Cardiovascular effects:** HD may cause hypotension, which is a risk in the unstable patient. PD and CRRT have few cardiovascular effects. CRRT can be used for the unstable patient.

---

**CRITICAL THINKING**

**Ms. Jackson**

Ms. Jackson is a single, 56-year-old woman with a 20-year history of type 1 diabetes, hypertension, hyperlipidemia, chronic anemia, and a total knee replacement. She has been diagnosed with CKD. She was admitted to a medical unit for treatment of shortness of breath and CKD. Treatment will include hemodialysis. She has had increasing shortness of breath, has pitting edema, urine output of about 375 mL/day, and is having premature ventricular contractions (PVCs) as seen on the cardiac monitor. Her admitting laboratory values are Na 131, K 6, Cl 97, Ca 10, iron (Fe) 64, WBC 4000, RBC 3.12, Hgb 10.1, Hct 32, creatinine 7, B UN 30. Her blood glucose levels yesterday were as follows: 07:00, 154 mg/dL; noon, 122 mg/dL; 17:00, 188 mg/dL. She has sliding-scale insulin ordered. She is having an echocardiogram and chest x-ray done. She is having a two-tailed subclavian catheter placed for blood access. She is withdrawn and quiet.

1. What would be the first thing the nurse would address after getting the report?
2. What do Ms. Jackson’s physical symptoms indicate and the laboratory values reflect?
3. What should the nurse say to Ms. Jackson in relation to her withdrawn behavior?
4. What should the nurse identify related to Ms. Jackson’s understanding of self-care?
5. What teaching is needed for the diagnostic tests?
6. What nursing care is required for the blood access?
7. What type of insulin is used for sliding-scale insulin coverage? Why?
8. With what members of the health team would the nurse anticipate collaborating?

*Suggested answers are at the end of the chapter.*
Kidney Transplantation

Kidney transplantation is another treatment for CKD and is extremely successful. An advantage of transplant compared with dialysis is that it reverses many of the physiological changes. The patient is also not dependent on dialysis and dietary restrictions.

A kidney transplant is a procedure in which a donor kidney is placed in the abdomen of a patient with CKD (Fig. 37.11). This healthy transplanted kidney functions as a normal kidney does. The donated kidney can come from a family member, a living, nonrelated donor, or a cadaver donor. Tissue and blood types must match so the body’s immune system does not reject the donated kidney. Patients receive drugs to help prevent rejection, which must be taken for the rest of the patient’s life. Sometimes even with these drugs, the body rejects the kidney, and the patient must go back on dialysis (“Cultural Considerations” and “Patient Perspective”).

Clinical trials that give the same donor’s bone marrow at the time of the kidney transplant to reduce rejection and the need for lifelong antirejection medications are in progress. Patients in the studies have been able to stop or greatly reduce their antirejection medications.

Cultural Considerations

Because many Vietnamese people believe that the body must be kept intact even after death, they may object to removal of body parts or organ donation. Jewish law views organ transplantation from the recipient, the living donor, the cadaver donor, and the dying donor differently.

Patient Perspective

Kidney Transplantation: Pat

My experience with a kidney transplant spans three decades, but my overall renal illness experience also spans several years of illness and dialysis before the transplant. I think the biggest changes I have seen over the years are the involvement of patients in their own care options, as well as increased technical advances that allow transplantation to be very successful. Some of the feelings one experiences before transplantation are fear, uncertainty, and—if awaiting a donor—the guilt of knowing someone must die before you can live.

More than 30 years ago, there were no support groups and no one to talk to except family and doctors. Today, there are many support mechanisms in place for patients and families both before and after transplantation. As a nurse, you can help patients by knowing these support resources for referral. After a transplant, it is wonderful to feel better, almost immediately. However, as wonderful as transplantation is, the side effects of the antirejection medications may be felt immediately, while other problems take years to develop. Unfortunately, no one escapes the side effects of the medications. I have had breast cancer, osteoarthritis, cataracts, ulcers, skin cancer, anemia, weight gain, and other side effects of prednisone and Imuran (azathioprine). However, I can assure you that I feel this is much better than the alternative of dialysis.

Nursing Process for the Patient With Kidney Disease

Data Collection

Kidney disease progressively affects all body systems. If AKI is short term, fewer effects may be seen because some effects will not develop. In CKD, more effects are seen because the disease has time to progress. Data should be collected for signs and symptoms in all body systems. Family history of kidney disease and patient history of health problems such as hypertension, diabetes, systemic erythematosus lupus, or urinary disorders are noted in the history. Also noted are medications the patient takes because they may be nephrotoxic and require adjustments. Recent changes in weight are documented.
NURSING CARE PLAN for the Patient With Chronic Kidney Disease

**Nursing Diagnosis:** Excess Fluid Volume related to kidney’s inability to excrete water

**Expected Outcomes:** Fluid volume will be stable as evidenced by stable weight, absence of edema, lung sounds clear, and blood pressure within the patient’s normal parameters.

**Evaluation of Outcomes:** Is weight stable? Is edema absent? Are lungs clear? Is blood pressure within the patient’s normal parameters?

**Intervention**
- Monitor weight daily at same time; report gain of more than 2 pounds. **Rationale** Those retaining fluid will have weight gain. **Evaluation** Is weight stable? Should HCP be notified of change?
- Monitor intake and output. **Rationale** This reveals degree of fluid retention. **Evaluation** Is output less than intake? Is this a change?
- Monitor and report shortness of breath, tachycardia, crackles in lungs, frothy sputum, heart irregularities, hypotension, cold clammy skin. **Rationale** These are symptoms of heart failure that may accompany fluid overload. **Evaluation** Are symptoms of heart failure present?
- Watch for new onset of jugular vein distention with patient’s head raised to 30- to 45-degree angle. **Rationale** Fluid overload causes right-sided heart failure, resulting in distended jugular veins. **Evaluation** Are jugular veins distended? Is this a new finding?
- Monitor vital signs, including orthostatic blood pressure. **Rationale** Blood pressure changes reflect fluid volume. **Evaluation** Is blood pressure increased?
- Monitor for edema. **Rationale** Edema is a symptom of fluid overload. **Evaluation** Is edema present? Is this a change?
- Monitor activity tolerance. **Rationale** Reduced activity tolerance may indicate heart failure related to fluid retention. **Evaluation** Is patient’s tolerance of activity stable? Worsening?
- Monitor serum protein and albumin levels. **Rationale** Low serum protein and albumin levels contribute to edema. **Evaluation** Are levels within normal limits?
- Maintain sodium and fluid restrictions (often 600 mL plus the previous day’s urine output) as ordered. Develop a plan with specific allotted amounts of fluid at each meal and for medications. Teach patient the importance of each. **Rationale** For those on dialysis, fluid intake is adjusted so that weight gains are no more than 1–3 kg between dialysis sessions. **Evaluation** Does patient understand and maintain sodium and fluid restriction?

**Nursing Diagnosis:** Impaired Skin Integrity related to dryness, excess fluid, crystal deposits

**Expected Outcome:** The patient will maintain intact skin.

**Evaluation of Outcome:** Does patient report no itching or dryness? Is patient’s skin intact?

**Intervention**
- Observe skin for open areas and signs of infection. **Rationale** Detects early signs of problems. **Evaluation** Is skin intact?
NURSING CARE PLAN for the Patient With Chronic Kidney Disease—cont’d

**Intervention** Bathe with tepid water, oils, or oatmeal. **Rationale** Bathe regularly to reduce crystals with nondrying items to reduce itching and dryness and promote comfort. **Evaluation** Does patient report no itching or skin dryness?

**Intervention** Apply lotion to skin after bathing. **Rationale** Lotion is used for itching to reduce dry skin. **Evaluation** Is skin dry?

**Nursing Diagnosis:** Activity Intolerance related to anemia secondary to impaired synthesis of erythropoietin by the kidneys

**Expected Outcome:** The patient will be able to perform activities important to him or her.

**Evaluation of Outcome:** Does patient state satisfaction with level of activity tolerance?

**Intervention** Assess for pale mucous membranes and skin color, dyspnea, chest pain. **Rationale** These are signs and symptoms of anemia. **Evaluation** Does patient exhibit symptoms of anemia?

**Intervention** Monitor hemoglobin (Hgb), hematocrit (Hct). **Rationale** Low hemoglobin and hematocrit indicate anemia. **Evaluation** Are Hgb and Hct within normal limits?

**Intervention** Watch for signs of bleeding. **Rationale** Bleeding will worsen anemia. **Evaluation** Are signs of bleeding present?

**Intervention** Administer erythropoietin as ordered. Assist with blood transfusion as needed. **Rationale** Erythropoietin stimulates production of RBCs by bone marrow. **Evaluation** Are Hgb and Hct rising with use of erythropoietin?

**Intervention** Have patient space activities with rest periods. **Rationale** Rest periods decrease demand for oxygen. **Evaluation** Is patient able to tolerate activities with rest periods?

**Nursing Diagnosis:** Risk for Injury related to bleeding tendency from platelet dysfunction and use of heparin during dialysis, and from tendency for GI bleeding

**Expected Outcomes:** The patient will not experience bleeding. If bleeding occurs, it will be recognized and stopped quickly.

**Evaluation of Outcomes:** Are signs and symptoms of bleeding absent or recognized and reported quickly?

**Intervention** Observe for and report blood in stool or emesis, easy bruising, bleeding from mucous membranes or puncture sites, and report immediately if present. **Rationale** Bleeding must be recognized quickly to prevent complications. **Evaluation** Does patient have signs of bleeding?

**Intervention** Monitor Hgb, Hct, clotting studies, and platelets, and report results. **Rationale** Declining Hgb and Hct indicate blood loss. Declining platelet count or rising clotting times indicate increased risk of bleeding. **Evaluation** Are lab results stable?

**Intervention** Monitor vital signs. **Rationale** Falling blood pressure and rising pulse may indicate volume deficit from bleeding. **Evaluation** Are vital signs stable?

**Intervention** Avoid giving injections if possible. **Rationale** Injections can cause bleeding into tissue. **Evaluation** Can medications be given by another route?

#### Nursing Diagnosis: Imbalanced Nutrition: Less Than Body Requirements related to restricted diet, anorexia, nausea, and vomiting, and stomatitis secondary to effect of excessive urea on the GI system

#### Expected Outcomes: The patient will maintain ideal weight, and serum protein and albumin levels will be within normal limits.

#### Evaluation of Outcomes: Are weight and lab values at desired levels?

| Intervention | Monitor weekly weight and serum protein and albumin levels. **Rationale** Weight and laboratory results provide information about nutrition status. **Evaluation** Are weight and laboratory values stable? |
**NURSING CARE PLAN for the Patient With Chronic Kidney Disease—cont’d**

**Intervention** Consult dietitian for low-protein diet planning and teaching. **Rationale** Low-protein diets decrease formation of waste products (urea, creatinine). **Evaluation** Does patient understand low-protein diet?

**Intervention** Initiate a calorie count—consult dietitian for assistance. **Rationale** A calorie count can provide information about the adequacy of the patient’s diet. **Evaluation** Is patient receiving adequate calories?

**Intervention** Provide frequent oral care. **Rationale** Oral care enhances appetite and reduces urine taste in mouth. **Evaluation** Does oral care enhance appetite?

**Intervention** Offer frequent small feedings and dietary supplements. **Rationale** Smaller feedings are better tolerated and reduce risk of nausea. **Evaluation** Does patient tolerate small feedings?

**Intervention** Offer medications ordered for nausea before meals. **Rationale** Nausea reduces appetite and must be controlled. **Evaluation** Are antiemetics effective?

**Intervention** Ensure bowel movement daily or according to patient’s usual pattern. **Rationale** Constipation can interfere with appetite. **Evaluation** Are patient’s bowels functioning normally for him or her?

---

**SUGGESTED ANSWERS TO CRITICAL THINKING**

**Mrs. Milan**
1. Sexual intercourse can be a predisposing factor to UTI, especially if the patient does not urinate after intercourse.
2. Mrs. Milan should be cautioned to always urinate after intercourse. (See also Box 37-1, “Patient Education”).
3. The urinalysis will show WBCs, bacteria, RBCs, and positive nitrites.
4. Teaching should include the need to take all of the medication until it is gone even if she feels better. The reason for this is to ensure that the infection is completely resolved so it does not return due to some remaining bacteria. She should return for a urine culture after the therapy is complete.

**Mr. Stevens**
1. Weight, intake and output, blood pressure, and laboratory tests should be assessed as part of the morning evaluation.
2. BUN, serum creatinine, and potassium levels should also be checked.
3. Mr. Stevens should be taught that he needs to take antihypertensive medications, keep his follow-up visits to his HCP, follow a low-sodium diet, and restrict fluids if ordered.

**Ms. Jackson**
1. Collect data related to Ms. Jackson’s breathing and respiratory status first. Then address the cardiovascular system to see how she is tolerating the dysrhythmia. Obtain Ms. Jackson’s weight and intake and output to monitor fluid balance.
2. Shortness of breath and pitting edema related to fluid overload; urine output 375 mL/day is due to CKD; PVCs are due to elevated K. Na is low due to dilutional effect of excess fluid. K is retained due to CKD. WBC low due to CKD. RBC, Hgb, Hct low due to anemia. Creatinine and BUN are not excreted and are elevated due to CKD. Blood glucose is elevated due to diabetes.
3. Therapeutic conversation suggestions: “Ms. Jackson, would you like to talk about your diagnosis?” “How do you feel about your diagnosis?” “Do you have questions or concerns?” “What are your usual coping methods?” Provide explanations for procedures and interventions.
4. Determine Ms. Jackson’s understanding of what CKD is, how it is treated, how to follow the renal diet and fluid restrictions, and the action and importance of medications. Identify barriers to self-care and her support systems.
5. Teaching includes that the chest x-ray and echocardiogram require no preparation and are not painful.
UNIT NINE  Understanding the Urinary System

SUGGESTED ANSWERS TO—cont’d

6. A two-tail subclavian blood access is dedicated for hemodialysis. It is not used for any other purpose. Monitoring includes observing the site for signs of infection: redness, warmth, swelling, tenderness, drainage, and fever.

7. Regular insulin is used because a rapid acting insulin affects blood glucose levels now. Sliding scale insulin is ordered at intervals to monitor and treat the current blood glucose level. So only regular insulin is used for a sliding scale insulin order.

8. The registered nurse, licensed practical nurse/licensed vocational nurse, surgeon, nephrologist, dietician, pharmacist, and social worker.

REVIEW QUESTIONS

1. The nurse is planning a teaching session for a patient on preventing urinary tract infections. Which of the following information should the nurse include in the teaching plan? **Select all that apply.**
   1. Void frequently.
   2. Drink large amounts of citrus juices.
   3. Eat large amounts of vegetables.
   4. Wash the perineum every 8 hours.
   5. Void after sexual intercourse.
   6. Avoid drinking cranberry juice.

2. The nurse is planning care for a patient who is admitted to the hospital with a diagnosis of a kidney stone. Which of the following interventions would the nurse implement?
   1. Restrict fluids.
   2. Strain all urine.
   3. Increase calcium intake.

3. The nurse is obtaining a history on a patient with a diagnosis of bladder cancer. Which of the following would the nurse expect to find in the patient’s history?
   1. Tobacco use
   2. Vegetarian diet
   3. Caffeine use
   4. Alcohol use

4. While changing the pouch at the stoma site of an ileal conduit, the nurse notes the stoma is constantly spilling urine. Which of the following actions should the nurse take?
   1. Notify the physician of the constant spillage.
   2. Continue changing the pouch.
   3. Remove the overflow of urine with a straight catheter.
   4. Irrigate the stoma with a sterile solution of normal saline.

5. The nurse is contributing to the plan of care for a patient with glomerulonephritis. Which of the following interventions would the nurse recommend be included in the patient’s plan of care?
   1. Increase fluid intake.
   2. Decrease sodium intake.
   3. Increase potassium intake.
   4. Decrease carbohydrate intake.

6. The nurse is caring for a postoperative patient who is receiving 0.9% normal saline IV at 125 mL/hour, morphine for pain control, and gentamicin (Garamycin) IV every 8 hours for 24 hours. The patient is allergic to iodine. Morning labs are WBC 8500, Hgb 12.4 g/dL, creatinine 2.2 mg/dL. Which of these findings is a priority for the nurse to report to the RN?
   1. WBC
   2. IV rate of 125 mL/hour
   3. Allergies
   4. Creatinine level

7. A patient with CKD who is on hemodialysis asks for a snack in the afternoon. The patient’s potassium level is elevated. Which of the following foods could be given? **Select all that apply.**
   1. Banana
   2. Gelatin dessert
   3. Clear carbonated beverage
   4. Cranberry juice
   5. Nectarine

8. The nurse is checking patency of a new right arm AV fistula. What action does the nurse use to do this?
   1. Auscultate the right brachial pulse.
   2. Auscultate and palpate the right radial pulse.
   3. Measure blood pressure in the right arm.
   4. Palpate for thrill and auscultate bruit over the fistula.
Chapter 37  Nursing Care of Patients With Disorders of the Urinary System  869

9. A patient is returning to the medical unit after a dialysis session. The nurse notes bleeding from the patient’s vascular access in the left arm. Which of the following is the nurse’s first action?
1. Call the physician.
2. Notify the dialysis nurse.
3. Apply pressure to access site.
4. Take patient’s blood pressure.

10. A patient is to receive 1600 mg of Renagel (sevelamer) orally with meals. Renagel 400-mg tablets are available. How many tablets should the nurse give?
Answer: ________________tablets

Answers can be found in Appendix C.

Understanding the Endocrine System
Endocrine System
Function and Assessment

KEY TERMS
affect (AF-fection)
exophthalmos (eks-off-THAL-mus)

LEARNING OUTCOMES

1. Identify the glands of the endocrine system.
2. Explain the function of each of the hormones in the endocrine system.
3. Describe the effects of aging on endocrine system function.
4. List data to collect when caring for a patient with a disorder of the endocrine system.
5. Plan nursing care for patients undergoing testing for an endocrine disorder.
The endocrine system consists of the endocrine (ductless) glands, which secrete hormones. Unlike other organ systems, the glands of the endocrine system are anatomically separate (Fig. 38.1). Their hormones are involved in fluid balance; metabolism, energy balance, growth, and development; contraction of smooth and cardiac muscle; glandular secretion; reproduction; and the establishment of circadian rhythms. Each hormone is secreted in response to a specific stimulus, is circulated by the blood, and affects target cells that have receptors for that hormone. Some hormones are secreted in response to hormones from other endocrine glands. Most hormone levels are regulated by negative feedback systems.

**Pituitary Gland**

The pituitary gland (hypophysis) is suspended by a short stalk from the hypothalamus in the brain (Fig. 38.2). There are two primary lobes or portions: anterior and posterior.

**Anterior Pituitary Gland**

The anterior pituitary gland secretes its hormones in response to releasing hormones from the hypothalamus (Fig. 38.3). It is responsible for producing the hormones it releases.

- Growth hormone (GH) increases cell division in tissues capable of mitosis. It also increases cellular uptake of amino acids for use in protein synthesis and releases fat from adipose tissue for energy production. Secretion of GH is regulated by growth hormone–releasing hormone (GHRH) and by growth hormone–inhibiting hormone (GHIH, or somatostatin), both from the hypothalamus. GHRH is produced during hypoglycemia or when there is a high blood level of amino acids. GHIH is secreted during hyperglycemia, when carbohydrates are available for energy production and the mobilization of fat is not needed.

- Throid-stimulating hormone (TSH) stimulates growth and secretions of the thyroid gland. TSH secretion is stimulated by thyrotropin-releasing hormone (TRH) from the hypothalamus when the metabolic rate decreases.

- Adrenocorticotropic hormone (ACTH) stimulates secretion of cortisol and related hormones from the adrenal cortex. Corticotropin-releasing hormone (CRH) from the hypothalamus stimulates the release of ACTH. CRH is produced during any type of stress such as injury disease, exercise, or hypoglycemia.

- See Figure 38.3 for other hormones of the anterior pituitary gland.

**Posterior Pituitary Gland**

The posterior pituitary gland stores and releases antidiuretic hormone (ADH; sometimes called vasopressin) and oxytocin (Fig. 38.4). Axon tracts from the hypothalamus transmit the hormones to the posterior pituitary and signal their release.

- ADH increases water reabsorption by the kidney tubules, which decreases urine output. The water is reabsorbed back into the blood, thereby maintaining normal blood volume and pressure. In cases of great fluid loss, such as severe hemorrhage, the large amount of ADH secreted is especially important because it causes arteriole vasoconstriction, which increases blood pressure to homeostatic levels.

- Oxytocin causes contractions of the myometrium to bring about delivery of a newborn and placenta. Release of oxytocin operates on a positive feedback loop. During breastfeeding, the subsequent release of oxytocin causes contraction of the smooth muscle cells around the mammary ducts. This release of milk is called milk ejection (or letdown).

**Thyroid Gland**

The thyroid gland consists of two lobes connected by a midpiece called the isthmus (Fig. 38.5). Three hormones are produced by the thyroid gland: triiodothyronine (T3), thyroxine (T4), and calcitonin.

- T3 and T4 increase cellular respiration of glucose and fatty acids, which increases the metabolic rate—that is, energy and heat production. They are essential for normal physical growth, mental development, and reproductive maturation. Sufficient iodine intake is required for T3 and T4 production.

- The direct stimulus for secretion oT3 and T4 is TSH from the anterior pituitary. A decrease in metabolic rate causes the
Despite its small size, the pituitary gland is actually two distinct glands: the anterior pituitary, or adenohypophysis, and the posterior pituitary, or neurohypophysis. These two glands are made of different tissue, excited by different types of stimuli, and secrete different hormones.

Neurons within the hypothalamus synthesize various hormones. Some, called releasing hormones, stimulate the anterior pituitary to secrete its hormones. Others, called inhibiting hormones, suppress hormone secretion by the anterior pituitary.

A stalk called the infundibulum connects the hypothalamus and pituitary.

Thyroid-stimulating hormone (TSH), or thyrotropin, stimulates the thyroid gland to secrete thyroid hormone.

Growth hormone (GH), or somatotropin, acts on the entire body to promote protein synthesis, lipid and carbohydrate metabolism, and bone and skeletal muscle growth.

Prolactin stimulates milk production in the mammary glands in females. In males, it may make the testes more sensitive to LH.

Luteinizing hormone (LH)—a gonadotropin—stimulates ovulation and estrogen and progesterone synthesis in females and the secretion of testosterone by the testes in males.

Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to secrete corticosteroids.

Follicle-stimulating hormone (FSH)—one of the gonadotropins—stimulates the production of eggs in the ovaries of females and sperm in the testes of males.

Chapter 38  Endocrine System Function and Assessment

The posterior pituitary holds the hormones until stimulated by the nervous system to release them. The nerve fibers that form the posterior pituitary originate in the hypothalamus. The hypothalamic neurons synthesize hormones, which they send down to the posterior pituitary to be stored. The posterior pituitary holds the hormones until stimulated by the nervous system to release them.

Antidiuretic hormone (ADH) acts on the kidneys to reduce urine volume and prevent dehydration. ADH is also called vasopressin.

Oxytocin stimulates contraction of the uterus during childbirth. It also triggers the release of milk from the breasts during lactation.

The thyroid gland resides in the neck, just below the trachea, where it is wrapped around the anterior and lateral portions of the trachea.

Thyroid tissue is made of tiny sacs called thyroid follicles. Each follicle is filled with a thick fluid called thyroid colloid. The cells lining the sacs secrete the two main thyroid hormones: T₃ (triiodothyronine) and T₄ (thyroxine). Unlike other glands, the thyroid gland can store the hormones for later use.

hypothalamus to secrete TRH. TRH stimulates the anterior pituitary to secrete TSH, which increases secretion of T3 and T4, which increase energy production and raise the metabolic rate. Negative feedback decreases the secretion of TRH from the hypothalamus until the metabolic rate decreases again.

The third thyroid hormone (TH), calcitonin, targets bone tissue and therefore is especially important during childhood when bone growth is accelerated. Calcitonin inhibits resorption of calcium and phosphate by osteoclasts, thereby lowering the blood levels of these minerals and retaining them in bones. This one function of calcitonin has two important results: the maintenance of normal blood levels of calcium and phosphate and the maintenance of a strong, stable bone matrix. The stimulus for secretion of calcitonin is hypercalcemia.

### LEARNING TIP

Learning tip: Confused between resorption and reabsorption? Resorption breaks down bone tissue and releases calcium ions into circulation when PTH is secreted. Reabsorption is the process of absorbing a substance into the blood again, such as when ADH causes water to be reabsorbed from the kidney tubules back into the blood supply.

### LEARNING TIP

An easy way to remember the function of calcitonin is to remember calciTONin TONes down serum calcium.

### Parathyroid Glands

There are usually four parathyroid glands, two on the back of each lobe of the thyroid gland (Fig. 38.6). They produce parathyroid hormone (PTH), an antagonist to calcitonin. Besides bone, the target organs of PTH are the small intestine and kidneys. The overall effect of PTH is to raise the blood calcium level and lower the blood phosphate level.

Homeostasis of blood calcium level is regulated by calcitonin and PTH. (See animation on DavisPlus.) Calcium ion delivery through the blood is essential for normal excitability of neurons and muscle cells and for the process of blood clotting.

### Adrenal Glands

The bilateral adrenal glands are located superior to each kidney. The inner adrenal medulla is surrounded by an outer adrenal cortex (Fig. 38.7).

#### Adrenal Medulla

The catecholamines (epinephrine and norepinephrine), released by the adrenal medulla, are sympathomimetic, meaning they mimic the sympathetic nervous system. During stress, the hypothalamus stimulates their release to prolong the body’s stress response.

#### Adrenal Cortex

The adrenal cortex secretes three types of steroid hormones: mineralocorticoids, glucocorticoids, and gonadocorticoids (“sex steroids”).

Aldosterone is the most abundant of the mineralocorticoids, and its target organs are the kidneys. Aldosterone increases the reabsorption of sodium ions and the excretion of potassium ions by the kidney tubules. As sodium ions are reabsorbed, hydrogen ions may be excreted in exchange. This is one mechanism to prevent the accumulation of hydrogen ions that would lead to acidosis. Also, as sodium ions are reabsorbed, water follows; this is important for maintaining normal blood volume and blood pressure.
Cortisol is the most abundant of the glucocorticoids and has many target tissues. It stimulates gluconeogenesis in the liver and increases lipolysis and protein catabolism for energy production. By providing energy sources to body tissues, cortisol ensures that glucose will be available for the brain (glucose-sparing effect). Cortisol release is increased during response to stress. The hypothalamus causes secretion of ACTH by the anterior pituitary, which increases cortisol secretion by the adrenal cortex. The resultant increase in energy availability is necessary for stress-induced changes. Cortisol also has an anti-inflammatory effect. However, excess cortisol decreases the immune response and can delay healing of damaged tissue.

The gonadocorticoids are small amounts of male androgens. In females they are converted to estrogens and are the only source of estrogen after menopause. In both genders, they contribute to libido.

Pancreas
The pancreas is both an exocrine and endocrine gland. As an endocrine gland, the pancreas secretes insulin and glucagon for blood glucose homeostasis, and somatostatin, which inhibits both insulin and glucagon (Fig. 38.8).

Hypoglycemia stimulates alpha cells to release glucagon. Glucagon raises blood glucose, making it available to cells.

Hyperglycemia stimulates beta cells to release insulin. Insulin increases the uptake of glucose from the blood into cells, lowering blood glucose. Cells use glucose in cellular respiration to release energy.

Hyperglycemia occurs after meals, especially those high in carbohydrates. Insulin and glucagon function as antagonists; normal secretion of both hormones ensures a blood glucose level that fluctuates within normal limits (Fig. 38.9). Table 38.1 (see p. 880) reviews endocrine hormone function.

Aging and the Endocrine System
Most of the endocrine glands decrease secretion with age, but normal aging usually does not lead to serious hormone deficiencies or illness (Fig. 38.10). Unless specific pathological conditions develop, the endocrine system continues to function adequately in old age.

**NURSING ASSESSMENT OF THE ENDOCRINE SYSTEM**

**Health History**
When performing a health history, a number of questions can be asked to determine whether an endocrine problem exists. Often, however, you might be a ware of a history of an endocrine disorder, such as diabetes or hypothyroidism. When a disorder exists or is suspected, you can do more focused data collection. Assessment of individual disorders is provided in Chapters 39 and 40. Table 38.2 offers general questions that can help you identify new problem areas. If the data reveal abnormalities, they should be reported to the registered nurse or health care provider (HCP).
UNIT TEN  Understanding the Endocrine System

878

The pancreas lies just behind the stomach, with its head tucked in the curve of the beginning of the small intestine (duodenum) and its tail reaching to the spleen.

Exocrine cells, called acini, secrete digestive enzymes into ducts that drain into the small intestine.

Interspersed with the exocrine cells are clusters of endocrine cells; these cells are called pancreatic islets or the islets of Langerhans. The pancreatic islets contain several different types of cells, the main ones being alpha cells, beta cells, and delta cells.

**Physical Examination**

The physical examination starts with height, weight, and vital signs. Compare findings with the patient’s baseline assessment if available. Table 38.3 includes common endocrine-related causes of physical examination abnormalities.

**Inspection**

Observe the patient for mood and affect (emotional tone) throughout the physical assessment. Inspect the neck for thyroid enlargement. Look for eyes that bulge (exophthalmos). Note posture, body fat, and presence of tremor. Observe skin and hair texture and moisture. Note the presence of a moon-like face or “buffalo hump” on the upper back. Observe the lower extremities for skin and color changes that might indicate circulatory impairment. See Table 38.3 for the rationales for these observations.

**Palpation**

The thyroid gland is the only palpable endocrine gland. The licensed practical nurse/licensed vocational nurse may assist a physician or nurse practitioner (NP) to palpate the thyroid gland. The practitioner stands behind or in front of the seated patient and palpates the gland while the patient swallows a sip of water. You can assist with positioning the patient, providing water, and instructing the patient to take a sip of water and hold it in his or her mouth until told to swallow. The thyroid gland should never be palpated in a patient with uncontrolled hyperthyroidism because this can stimulate secretion of additional TH.

Palpate all peripheral pulses. The posterior tibial and dorsalis pedis pulses may be diminished in patients with circulatory impairment. Palpate skin turgor by gently pinching a small piece of skin. The sternum is a good place to check. If a “tent” of skin remains in place, the patient may be dehydrated as a result of water loss, as in ADH deficiency.

**Auscultation and Percussion**

Auscultation and percussion are not usually part of an endocrine assessment.

**WORD BUILDING**

exophthalmos: exo—outward + ophthalmos—relating to the eye

- **physical**: having to do with the body or its functions
- **examine**: to look carefully at something
- **enlargement**: increase in size
- **tremor**: a shaking movement of a part of the body
- **turgor**: the condition of being taut or firm
- **circulatory**: related to the circulation of blood
- **palpate**: to touch or press with the fingers to feel
- **auscultate**: to listen with a stethoscope
- **percussion**: to tap lightly on a part of the body to feel for resonance
After eating, blood glucose levels rise as glucose flows from the digestive tract into the bloodstream.

When blood glucose levels drop below a certain point (such as after skipping a meal), the alpha cells of the pancreas release glucagon into the blood. Glucagon stimulates the liver to break down stored glycogen into glucose, which it then releases into the bloodstream. This causes blood glucose levels to rise.

Glucagon stimulates the liver to break down stored glycogen into glucose, which it then releases into the bloodstream. This causes blood glucose levels to rise.

High glucose levels stimulate the beta cells of the pancreas to secrete insulin.

Insulin triggers two reactions:
1. It stimulates the cells to take up more glucose.
2. It causes the liver to take up glucose and store it as glycogen.

The combined result is that glucose levels return to normal levels.

Stimulation Tests
Stimulation tests may also help determine endocrine gland function. For this type of test, a substance is injected to stimulate a gland. The hormone secreted by that gland is then measured in the blood to determine how well it responded to the stimulation. For example, in a TRH stimulation test, TRH is injected. If the pituitary gland responds appropriately, TSH is secreted. If the thyroid gland responds appropriately to the TSH, T3 and T4 levels rise. Failure of TRH to stimulate TSH

**TABLE 38.1 REVIEW OF ENDOCRINE FUNCTION—cont’d**

Continued
and TH indicates a pituitary or thyroid condition. Further studies might be done to determine the cause.

**Suppression Tests**

Suppression tests are the opposite of stimulating tests. For this type of test, a substance is injected that is expected to suppress a hormone’s release. For example, if dexamethasone (a steroid hormone) is injected, cortisol release from the adrenal cortex is expected to be suppressed via a negative feedback mechanism. If the cortisol level is not suppressed, adrenal cortex dysfunction is suspected.

**Urine Tests**

Sometimes it is helpful to measure the amount of hormone or hormone by-product excreted in the urine during a 24-hour period. Examples are cortisol and vanillylmandelic acid, a product of catecholamine metabolism. See DavisPlus for the procedure for collecting a 24-hour urine specimen.

**Other Laboratory Tests**

Some laboratory tests may indirectly reflect the function of an endocrine gland. For example, a serum calcium level helps indicate PTH or calcitonin secretion, and a blood glucose level reflects insulin secretion.

**Nuclear Scanning**

**Thyroid Scan**

A thyroid scan may be done to determine the presence of tumors or nodules. For this test, a radioactive material is given orally or by injection. The material is taken up by the thyroid gland. After a specified time, the thyroid gland is scanned with a scintillation camera. The scan will show hot spots (nodules), which are not malignant, or cold spots (areas that

<tbody>
<tr>
<td><strong>Neuromuscular</strong></td>
<td>Have you noticed muscle spasms or twitching?</td>
<td>These symptoms may be associated with excessive antidiuretic hormone secretion (SIADH) or calcium depletion resulting from hypoparathyroidism.</td>
</tr>
<tr>
<td></td>
<td>Do you have numbness, tingling, or pain in your feet, legs, or hands?</td>
<td>These can be associated with neuropathy resulting from diabetes mellitus. Numbness and tingling can also indicate hypocalcemia related to hypoparathyroidism.</td>
</tr>
<tr>
<td><strong>Nutrition/Fluid Balance</strong></td>
<td>Have you gained or lost weight without trying?</td>
<td>Actual weight gain may be associated with hypothyroidism. Weight gain due to water retention may result from Cushing’s syndrome or SIADH.</td>
</tr>
<tr>
<td></td>
<td>Have you noticed excessive thirst or urination?</td>
<td>Excessive thirst and urination are classic symptoms of diabetes mellitus and diabetes insipidus.</td>
</tr>
<tr>
<td></td>
<td>Have you noticed a change in your energy level?</td>
<td>Lack of energy may be associated with uncontrolled diabetes, hypothyroidism, hyperthyroidism, Addison’s disease, or pituitary disorders.</td>
</tr>
<tr>
<td><strong>Metabolic</strong></td>
<td>Do you generally tolerate changes in environmental temperature?</td>
<td>Hypothyroidism can cause cold intolerance. Hyperthyroidism can cause heat intolerance.</td>
</tr>
<tr>
<td><strong>Mood/Memory</strong></td>
<td>Have you noticed a change in your mood or memory?</td>
<td>Mental function may be dull with hypothyroidism. Mood swings can occur with Cushing’s syndrome. Agitation or confusion can result from hypoglycemia in a person with diabetes.</td>

**Radioactive Iodine Uptake**

A radioactive iodine uptake test is similar to a thyroid scan and is done to evaluate thyroid function. Several scans are taken over a 24-hour period after administration of radioactive iodine. The amount of iodine taken up by the thyroid indicates the

---

...do not take up the radioactivity), which indicate malignancy. Cold spots can then be biopsied to confirm a diagnosis. Because such a small amount of radioactive material is used, the risk to the patient is minimal. The patient should be aware that the test takes approximately 30 minutes to complete.

SIADH = syndrome of inappropriate antidiuretic hormone.<br>*All normal values are for a fasting test.
activity of the gland. This is especially helpful in diagnosing hyperthyroidism.

**PET Scan**
Positron emission tomography (PET) scanning is another type of scan that can be done to differentiate between benign and malignant endocrine tumors. PET scans are helpful because they can show metabolic changes in organs or tissues.

**Radiographic Tests**
A computed tomography (CT) scan or magnetic resonance imaging (MRI) may be done to locate a tumor or identify hypertrophy of a gland.

---

**Ultrasound**
Ultrasound may be done of the thyroid or parathyroid glands to determine if they are enlarged or to find masses.

**Biopsy**
Biopsy is done to obtain tissue to examine for possible cancerous cells. The thyroid gland can be biopsied either by needle aspiration under local anesthesia or using a surgical incision.

---

**SUGGESTED ANSWERS TO**

**CRITICAL THINKING**

**Ms. Hackworth**
1. “It’s not your thyroid hormone that is high, it’s your thyroid-stimulating hormone. That means your pituitary gland has to work extra hard to try to stimulate your thyroid gland.”
2. 
   
   \[
   \frac{50 \text{ mcg}}{1000 \text{ mcg}} = 0.05 \text{ mg}
   \]

---

**REVIEW QUESTIONS**

1. Which hormones are secreted by the posterior pituitary gland? **Select all that apply.**
   1. Antidiuretic hormone
   2. Thyroid-stimulating hormone
   3. Growth hormone
   4. Luteinizing hormone
   5. Oxytocin
   6. Calcitonin

2. A patient is started on levothyroxine (Synthroid) to replace \( T_4 \) for a new diagnosis of hypothyroidism. What effect can the patient expect as the medication begins to work?
   1. Increased urination
   2. Improved blood sugar
   3. Lower blood pressure
   4. Increased energy

3. Which nursing action is appropriate when assisting an HCP with palpation of the thyroid gland during a routine physical examination?
   1. Ask the patient to take a deep breath.
   2. Give the patient a sip of water.
   3. Have the patient look up toward the ceiling.
   4. Help the patient to lie back on a pillow.

4. The nurse is doing an admission assessment on a new resident to an extended care facility. The patient’s face and shoulders seem to have a lot of fat, but the patient’s arms and legs are thin. Which of the patient’s routine medications might be involved?
   1. Prednisone (Deltasone, a glucocorticoid)
   2. Calcitonin
   3. Insulin
   4. Thyroid hormone (levothyroxine/Synthroid)

5. When explaining a thyroid scan to a patient, which of the following statements is correct?
   1. “You will take a special pill, and then an ultrasound will be taken of your neck.”
   2. “You will receive an injection of radioactive material, and then a special camera will take pictures of your thyroid gland.”
   3. “You will be placed into a special machine, and x-rays will be taken of your neck. It may be noisy.”
   4. “You will be given a special drink, and then magnetic energy is used to visualize the thyroid area.”

Answers can be found in Appendix C.

![DavisPlus!](davispl.us/medsurg5)
LEARNING OUTCOMES

1. Identify disorders caused by variations in the hormones of the pituitary, thyroid, parathyroid, and adrenal glands.
2. Explain the pathophysiology of each of the endocrine disorders presented.
3. Describe the etiologies, signs, and symptoms of each of the endocrine disorders.
4. Describe current therapeutic measures used for each of the selected endocrine disorders.
5. List data to collect when caring for patients with each of the endocrine disorders discussed.
6. Plan nursing care for patients with each of the disorders.
7. Explain how you will know if nursing interventions have been effective.

polyuria (PAH-lee-YOO-ree-ah)
tetany (TEH-nee)
The endocrine system is subject to a variety of disorders. Although the causes vary, the pathophysiology usually involves either too little or too much hormone activity. Insufficient hormone activity may be the result of hypofunction of an endocrine gland or insensitivity of the target tissue to its hormone. Excessive hormone activity may be the result of a hyperactive gland, ectopic hormone production, or self-administration of too much replacement hormone (Table 39.1). If you can remember the function of each hormone in the body, understanding the problems involved with an altered amount of each hormone becomes easier.

Most endocrine disorders are either primary or secondary. A primary disorder is a problem within the gland that is out of balance. Secondary disorders are caused by problems outside the gland, such as an imbalance in a tropic hormone, certain drugs, trauma, or surgery, or a problem in the feedback mechanism. For example, if the thyroid gland is diseased and causing hypothyroidism, it could be considered a primary problem. Sometimes hypothyroidism is caused by a lack of thyroid-stimulating hormone from the pituitary gland, even though the thyroid gland is healthy. This would be considered a secondary problem.

### LEARNING TIP

If you can remember what each hormone does in the body, it will be easier to remember what results from imbalances of that hormone. Most symptoms of hormone hyperactivity are the opposite of symptoms of that hormone’s hypoactivity.

### PITUITARY DISORDERS

Pituitary disorders often involve several hormone imbalances at once, caused by general hypopituitarism or hyperpituitarism. Problems involving all of the pituitary hormones at once, however, are rare. For simplicity, imbalances are considered separately here.

### Disorders Related to Antidiuretic Hormone Imbalance

Antidiuretic hormone (ADH; also called arginine vasopressin [AVP]) is synthesized in the hypothalamus and stored and secreted by the posterior pituitary gland. Recall that ADH is responsible for reabsorption of water by the distal tubules and collecting ducts in the kidneys. A decrease in ADH activity results in diabetes insipidus (DI). An increase in ADH activity is called syndrome of inappropriate antidiuretic hormone (SIADH). Table 39.2 compares DI and SIADH. Note how symptoms of too little ADH (water loss) are the opposite of symptoms of too much ADH (water retention).

### Diabetes Insipidus

#### PATHOPHYSIOLOGY.

DI is caused by a deficiency of ADH. If ADH is lacking, adequate reabsorption of water is prevented, leading to diuresis. In nephrogenic DI, there is enough ADH but the kidneys do not respond to it. Patients can urinate from 3 to 15 L per day. This leads to dehydration and increased serum osmolality (concentrated blood). The increased osmolality and decreased blood pressure normally trigger ADH secretion, which causes water retention and dilutes the blood; in patients with DI, this does not happen. Increased osmolality also leads to extreme thirst, which usually causes the patient to drink enough fluids to maintain fluid balance. In an unconscious patient or a patient with a defective thirst mechanism, however, dehydration can quickly occur if the problem is not recognized and corrected.

#### ETIOLOGY.

DI has a variety of causes. Tumors, trauma, or other problems in the hypothalamus or pituitary gland can lead to decreased production or release of ADH. Surgery in the area of the pituitary and certain drugs, such as glucocorticoids or alcohol, can also cause DI. Nephrogenic DI is diagnosed when the kidneys do not respond to ADH. It can be triggered by certain drugs or neoplasms, or by damage to the kidneys from pyelonephritis, polycystic disease, or other causes. Primary DI, sometimes called primary polydipsia, can cause polydipsia and polyuria with no clear cause. Sometimes patients drink excessive amounts due to dry mouth.

#### SIGNS AND SYMPTOMS.

The patient with DI urinates frequently (polyuria), and nighttime urination (nocturia) is present. This results in high serum osmolality and low urine osmolality. Urine specific gravity is decreased, making the urine dilute and light in color.

The patient experiences extreme thirst (polydipsia), and consumes large volumes of water. Often patients crave ice-cold water. If urine output exceeds fluid intake, dehydration occurs, with characteristic symptoms of hypotension, poor skin turgor, and weakness. Hypovolemic shock occurs if fluid...
balance is not restored. Dehydration and electrolyte imbalances result in a decrease in level of consciousness and death if the problem is not corrected.

The patient with DI may develop an enlarged bladder and kidney damage from constantly trying to “hold” too much urine.

DIAGNOSTIC TESTS. Diagnosis is based initially on a history of risk factors and reported symptoms. Urine specific gravity will be less than 1.001 (normal: 1.001–1.029) and can be monitored by laboratory tests or by using reagent strips at the bedside. Plasma and urine osmolality are measured and compared with each other. The actual amount of sodium in the blood may be normal, but it appears elevated in relation to the decreased amount of water. Computed tomography (CT) scanning or magnetic resonance imaging (MRI) are used to determine if a pituitary tumor is present.

A water-deprivation test may be done. For this test, the patient is deprived of water for up to 6 hours. Body weight and urine osmolality are tested hourly. If the urine continues to be diluted, even though the patient is not drinking and is losing weight as a result of volume depletion, DI is suspected. In the second stage of the test, the patient receives an injection of ADH, with a final urine test done 1 hour later. If the DI is nephrogenic, the kidneys will not respond to the injected ADH.

ADH levels can be measured in plasma or urine after administration of hypertonic saline or fluid restriction. The normal response would be elevated ADH; if it is not elevated, DI is suspected. The urine glucose level may also be checked to rule out diabetes mellitus.

THERAPEUTIC MEASURES. Hypotonic intravenous (IV) fluids such as 0.45% saline solution may be ordered to replace intravascular volume without adding extra sodium. IV fluids are especially important if the patient is unable to take oral fluids.

Medical treatment of DI involves replacement of ADH. In patients who require long-term therapy, synthetic ADH (desmopressin, or DDAVP) can be administered orally, subcutaneously or intranasally. Thiazide diuretics may decrease urine flow in the absence of ADH (even though they usually are used to increase urine output!). ADH replacement won’t help if the cause is nephrogenic; these patients may be placed on a low sodium diet and advised to drink plenty of water. Drugs such as chlorpropamide (Diabinese) can help the kidneys respond better to ADH. If a pituitary tumor is involved, treatment usually involves removal of the pituitary gland (hypophysectomy).

NURSING PROCESS FOR THE PATIENT WITH DIABETES INSIPIDUS.

Data Collection. When collecting data for a patient with DI, pay special attention to fluid balance. Daily weights are the most reliable method for monitoring the amount of fluid that is being lost. Taking accurate intake and output (I&O) measurements is also helpful. Skin turgor will be poor, and mucous membranes will be dry and sticky if the patient is becoming dehydrated. Monitor skin integrity because dehydration increases risk of breakdown. Monitor vital signs for signs of shock. Use a reagent strip (dipstick) or Urinometer to measure urine specific gravities. Monitor serum electrolytes and osmolality as ordered, and watch for changes in level of consciousness. Assess the patient’s understanding of his or her disease and treatment. Once treatment is initiated, continue to monitor fluid balance, being especially alert to signs of fluid overload.

Nursing Diagnoses, Planning, and Implementation. Deficient Fluid Volume related to failure of regulatory mechanisms.

Expected Outcome. The patient’s fluid balance will be maintained as evidenced by urine specific gravity between

hypophysectomy: hypophysis—pituitary + ectomy—surgical removal
UNIT TEN Understanding the Endocrine System

1,001 and 1,029, skin turgor within normal limits, and stable daily weight.

• Monitor daily weight, I&O, vital signs, and urine specific gravity. Decreased weight, output greater than intake, low blood pressure, elevated pulse rate, and high urine specific gravity can all indicate fluid deficit.

• Monitor patient for restlessness or weakness. These can indicate significant fluid deficit.

• Provide free access to oral fluids. If the patient’s thirst mechanism is not intact, give the patient fluids every hour. Oral fluids are essential to replace the excess lost in diuresis. If the patient is alert with an intact thirst mechanism, he or she can usually manage this independently.

• Encourage the patient to participate in maintaining I&O records, monitoring weight, and checking urine specific gravity, if able. This involves the patient and helps prepare him or her for self-monitoring at home.

• Report a significant drop in blood pressure and a rising pulse to the registered nurse or physician because these may be signs of hypovolemic shock.

• Teach the patient the importance of monitoring daily weights at home; losses or gains of greater than 2 pounds in a day should be reported to the physician. Weight loss or gain can indicate fluid imbalance and the need for a change in medication regimen.

• Advise the patient to wear identification, such as a medical alert bracelet, that identifies the disorder. Faster treatment can be initiated if emergency personnel are aware of a DI diagnosis.

Evaluation. If treatment has been effective, signs of dehydration will be absent, and weight and vital signs will be stable.

Syndrome of Inappropriate Antidiuretic Hormone
PATHOPHYSIOLOGY. SIADH results from too much ADH in the body. This causes excess water to be reabsorbed by the kidney tubules and collecting ducts, leading to decreased urine output and fluid overload. As fluid builds up in the bloodstream, osmolality decreases, and the blood becomes diluted. Normally, a decreased serum osmolality inhibits release of ADH. In SIADH, however, ADH continues to be released, adding to the fluid overload.

ETIOLOGY. Some cancers, such as pancreatic cancer or some types of lung cancer, may be ectopic sites of production of an ADH-like substance. Drugs such as certain antidepressants, chemotherapy, or general anesthetic agents can increase ADH secretion. Neurologic problems such as central nervous system (CNS) infections or a brain tumor affecting pituitary function can also cause SIADH. It may also be a complication of DI treatment.

SIGNS AND SYMPTOMS. Symptoms of SIADH include symptoms of fluid overload, such as weight gain (usually without edema) and dilutional hyponatremia (Box 39-1). The actual amount of sodium in the blood may be normal but appear to be low because of the diluting effect of the extra fluid. Serum osmolality is less than 275 mOsm/kg. The urine is concentrated because water is not being excreted. Electrolyte imbalance can cause muscle cramps and weakness. Because the osmolality of the blood is low, fluid can leak out of the vessels and cause brain swelling. If untreated, this results in lethargy, confusion, seizures, coma, and death.

DIAGNOSTIC TESTS. Serum sodium and osmolality are low, and urine sodium and osmolality are high. Serum ADH is high. Additional testing may be done to diagnose and locate an ADH-secreting tumor.

THERAPEUTIC MEASURES. Treatment is aimed at the underlying cause. If a tumor is secreting ADH, surgical removal may be indicated. Symptoms can be alleviated by restricting fluids to 800 to 1000 mL per 24 hours. Hypertonic saline fluids may be administered IV, and oral salt may be encouraged to maintain the serum sodium level. A loop diuretic such as furosemide (Lasix) increases water excretion. A vasopressin receptor antagonist such as conivaptan (Vaprisol) may be used to block the action of ADH in the kidney.

NURSING PROCESS FOR THE PATIENT WITH SIADH.

Data Collection. Excess fluid volume with hyponatremia is the primary concern for the patient with SIADH. To monitor fluid balance, assess vital signs, daily weight, I&O, urine specific gravity, and skin turgor. Edema and pulmonary crackles are not typically present. Determine the patient’s ability to maintain a fluid restriction. Assess level of consciousness and neuromuscular function. Monitor laboratory tests, including serum sodium level, as ordered by the physician. Assess the patient’s understanding of the disease process and treatment.

Nursing Diagnoses, Planning, and Implementation.

Excess Fluid Volume related to compromised regulatory mechanism

EXPECTED OUTCOME: The patient’s fluid balance will be maintained as evidenced by weight, I&O, and serum sodium within normal limits.

• Monitor daily weight, I&O, vital signs, and laboratory values. Increased weight, intake greater than output,
elevated blood pressure, bounding pulse, crackles, and low serum sodium may all indicate fluid overload.  
- Maintain fluid restriction as ordered to reduce serum dilution and normalize serum sodium.  
- Offer small amounts of fluids high in sodium, such as broth, cola, or tomato juice, as ordered. These may help correct dilutional hyponatremia.  
- Offer hard candy to reduce sensation of thirst.  
- Provide ice chips (count as half the volume of fluid; that is, 100 mL of ice chips equal approximately 50 mL of water). Ice chips take longer to consume than water and may be more satisfying to some patients.  
- Provide calibrated cups to help the patient maintain the restriction independently if able.  
- Allow the patient to participate in planning the types and times of fluid intake. Fluid restrictions are not pleasant for patients; patients who feel in control may be more likely to comply with restriction.  
- Report a change in level of consciousness immediately, and monitor the patient for seizures. These are signs of serious fluid imbalance.  
- Instruct the patient to report any weight gain greater than 2 pounds in 1 day, a change in urine output, or acute thirst. These are signs of fluid overload or risk for overload.  
- Encourage use of medical alert bracelet or other identification so emergency personnel will have information if needed.

**Evaluation.** Weight should stabilize at the pre-illness level once treatment is begun. Serum sodium level should be within normal limits.

**Growth Hormone Deficiency**

**PATHOPHYSIOLOGY.** When GH is deficient in childhood, a condition called short stature occurs. In the past, this was referred to as dwarfism (see Fig. 39.1). A deficiency of GH in adults does not affect growth, but in recent years, it has been found to have important functions even during adulthood.

**ETIOLOGY.** GH deficiency may be due to tumors, surgery, or trauma to the pituitary or hypothalamus. It may also be deficient in some cases of neglect or severe emotional stress. Malnutrition is the most common cause worldwide. Sometimes the cause is not known (“Cultural Considerations”).

**SIGNS AND SYMPTOMS.** Children may grow to only 3 to 4 feet in height but have normal body proportions. Sexual maturation may be slowed, related to involvement of additional pituitary hormones. Short stature in children is sometimes accompanied by mental retardation.

**CRITICAL THINKING**

**Mrs. Jackson**

- You are caring for Mrs. Jackson, a 78-year-old woman who has just returned to your unit after hip surgery. During the next 2 days, you notice that her weight increases from 118 to 124 pounds and she seems lethargic, but the nurse’s report didn’t indicate concern about it. You check her ankles and sacrum for edema but find none. In the afternoon, her son rushes out of the room and tells you she is becoming confused, adding that this is not like her at all.

1. What assessment should you do?  
2. What do you suspect?  
3. What should be your next steps?  
4. Based on her weight gain, about how much water is Mrs. Jackson retaining?

*Suggested answers are at the end of the chapter.*

**Disorders Related to Growth Hormone Imbalance**

Growth hormone (GH), also called somatotropin, is responsible for normal growth of bones, cartilage, and soft tissue.  

GH is synthesized and secreted by the anterior pituitary gland. An excess or deficiency of GH may be related to a more generalized problem with the pituitary gland or hypothalamus. A deficit of GH results in short stature if not corrected in childhood, and a variety of problems in adulthood. Excess GH results in gigantism (Fig. 39.1) or acromegaly.

In adults, symptoms of GH deficiency include fatigue, weakness, excess body fat, decreased muscle and bone mass, sexual dysfunction, high cholesterol, and increased risk for cardiovascular and cerebrovascular disease. Headaches, mental slowness, and psychological disturbances may also occur. All of these signs and symptoms can lead to decreased quality of life.

**DIAGNOSTIC TESTS.** Growth hormone levels in the blood can be measured by a routine laboratory test, but the results may be unreliable because GH is not evenly secreted over the course of a day. A more reliable test is a growth hormone stimulation test that measures GH in response to induced hypoglycemia. An MRI scan can help determine the presence of a tumor; radiographic studies may be used to determine bone age. Genetic testing may also be done.

**THERAPEUTIC MEASURES.** Treatment of GH deficiency is administration of growth hormone. In the past, GH was derived from human pituitary glands, so treatment was expensive and risky. Now GH (somatotropin [Humatrope]) can be made in a laboratory using recombinant DNA technology, so it is more readily available to those who need it. It is administered by subcutaneous injection. Surgery may be indicated if a tumor is the cause.

**NURSING PROCESS FOR THE PATIENT WITH GROWTH HORMONE DEFICIENCY.**

**Data Collection.** Assessment of the adult with GH deficiency includes mental status, ability to cope with the effects of the disorder, and understanding of the treatment plan. Also assess for signs of cardiovascular disease and other complications of the disorder.

**Nursing Diagnoses, Planning, and Implementation.** If the problem has been present since childhood, most related problems will not be new to the patient. The priority for the nurse, then, is to approach the patient with respect while assessing current problems that may need attention. Nursing diagnoses in the adult with GH deficiency will depend on assessed needs. These may include diagnoses such as Risk for Ineffective Self Health Management (see below), Fatigue, Knowledge Deficit, Imbalanced Nutrition, Risk for Injury, or Risk for Spiritual Distress.

An excellent resource for people with short stature is the Little People of America organization, found at www.lpaonline.org.

**Risk for Ineffective Self-Health Management related to knowledge deficit**

**EXPECTED OUTCOME:** The patient will have requisite knowledge to be able to manage self-care as evidenced by statement and demonstration of self-care activities.

- Assess patient’s understanding of his or her disease process and treatment. *Teaching should build on baseline knowledge.*
- Explain and demonstrate self-care measures as needed to the patient, including administration of GH injections. *The patient must understand the treatment to participate in it.*
- Help the patient explore the meaning of the disorder. *Talking about the disorder may help the nurse and patient identify needs that can be addressed.*

**Evaluation.** Nursing care has been effective if the patient is able to demonstrate self-administration of GH and describe plans for related self-care activities.

**CRITICAL THINKING**

**Adoption**

- Three siblings were adopted to a loving home after having been in several foster homes. After a year in their new home, each child suddenly grew 6 to 8 inches. What do you think happened?

*Suggested answers are at the end of the chapter.*

**Acromegaly**

Acromegaly is a rare excess of GH that affects adults, usually in their 30s or 40s. If GH excess occurs in children, the condition results in gigantism.

**PATHOPHYSIOLOGY.** Acromegaly occurs as a result of overproduction of GH in an adult. Bones increase in size, leading to enlargement of facial features, hands, and feet. Long bones grow in width but not length because the epiphyseal disks are closed. Subcutaneous connective tissue increases, causing a fleshy appearance. Internal organs and glands enlarge. Impaired tolerance of carbohydrates leads to elevated blood glucose.
ETIOLOGY. Excess secretion of GH can be caused by pituitary hyperplasia, a benign pituitary tumor, or excess of GH-releasing hormone (GH-RH) due to hypothalamic dysfunction. Sometimes tumors in other parts of the body secrete ectopic GH or GH-RH.

SIGNS AND SYMPTOMS. Symptoms develop very slowly, and the disorder may be present for years before it is recognized. Often the first symptom noticed is a change in ring or shoe size. The nose, jaw, brow, hands, and feet enlarge (Fig. 39.2). The teeth may be displaced, causing difficulty chewing, or dentures may no longer fit. The tongue becomes thick, causing difficulty in speaking and swallowing (dysphagia). The patient may develop sleep apnea. Vertebral changes can lead to kyphosis. Visual disturbances can occur because of tumor pressure on the optic nerve. Headaches result from tumor pressure on the brain. Diabetes mellitus may develop because GH increases blood glucose and causes an increased workload for the pancreas. (see Chapter 40). Osteoporosis and arthritis may occur. Erectile dysfunction may occur in men and amenorrhea in women. With treatment, soft tissues reduce in size, but bone growth is permanent.

DIAGNOSTIC TESTS. Serum growth hormone levels are measured, and radiographs show abnormal bone growth. GH may also be measured after a large dose of oral glucose. Normally, glucose suppresses GH release. If it continues to be released even after a glucose load, acromegaly is suspected. A CT scan or an MRI is done to locate a pituitary tumor.

THERAPEUTIC MEASURES. Treatment is aimed at the cause. Lanreotide (Somatuline Depot) or octreotide (Sandostatin) are injectable medications that mimic the body’s natural somatostatin and will decrease GH levels. Bromocriptine (Parlodel) is a pill that can lower GH. Pegvisomant (Somavert) blocks the effect of GH on receptor sites.

Hypophysectomy or radiation may be indicated if a tumor is the cause. If the pituitary is removed, lifelong replacement of thyroid hormone (TH), corticosteroids, and sex hormones is important to maintain homeostasis.

Pituitary Tumors

Most tumors of the pituitary gland are benign adenomas. However, even benign tumors in the brain can cause many symptoms, including visual disturbances, symptoms of increased pressure in the brain, and symptoms related to hormone imbalances, as described earlier. Treatment for pituitary tumors is usually hypophysectomy (surgical removal of the pituitary gland). Radiation may also be used, either alone or as an adjunct to surgery.

Nursing Care of the Patient Undergoing Hypophysectomy

Removal of the pituitary gland is called hypophysectomy. The procedure is most often done using minimally invasive endoscopic surgery, via the nose or a small incision just under the upper lip. This allows access through the sphenoid sinus to the pituitary gland, without disturbing brain tissue. Figure 39.3

WORD BUILDING

hyperplasia: hyper—excessive + plasia—formation or deviation
amenorrhea: a—not + men—month + orrhea—flow
shows the transsphenoidal approach to the gland through the upper lip. Some large tumors may need removal via transfrontal craniotomy (entry through the frontal bone of the skull).

**PREOPERATIVE CARE.** Make sure the patient understands the physician’s explanation of surgery. Perform and document a baseline neurological assessment. Prepare the patient for what to expect following surgery. Explain that it will be important after surgery to avoid any actions that increase pressure on the surgical site, such as coughing, sneezing, nose blowing, straining to move bowels, or bending from the waist. Because coughing can raise intracranial pressure and is therefore contraindicated, instruct the patient in deep-breathing exercises or use of an incentive spirometer. Patients can usually expect to stay in the hospital about a day.

**POSTOPERATIVE CARE.** Perform routine neurologic assessments to monitor the patient for changes from the baseline assessment. Also be sure to check urine for specific gravity because DI can occur following pituitary surgery. If a patient has had transsphenoidal surgery, nasal packing and a “mustache dressing” will be present. These are left in place and not removed unless ordered by the physician. Monitor the dressing for signs of cerebrospinal fluid (CSF) leakage. CSF contains glucose, so glucose testing strips can be used to determine if drainage is actually CSF or just nasal discharge. Remind the patient to avoid any actions that increase pressure on the surgical site. The patient is placed on hormone replacement therapy after hypophysectomy. Pituitary hormones are difficult to replace, so target hormones are generally given. These may include TH, glucocorticoids, intranasal desmopressin, and sex hormones.

**PATIENT EDUCATION.** Instruct the patient before discharge according to agency guidelines. These usually include instructions to prevent increased pressure on the surgical site, as well as instructions on how to administer the hormones and side effects to report. Examples include:

- Expect a small amount of bloody or mucous drainage from your nose.
- If you must blow your nose, do so very gently. Blowing can injure the surgical site and cause bleeding or spinal fluid leakage.
- Take stool softeners as needed to prevent straining for bowel movements.
- Take cough suppressants as directed to prevent coughing.
- If an upper lip incision was used, wait until the incision line is healed to brush teeth with a toothbrush. Floss and mouth rinses can be used instead.
- Take all medications as prescribed. You will be on hormone therapy to replace the hormones made by your pituitary gland.
- Call immediately if you develop a fever, if you have more than a small amount of blood drainage from the incision site, if you have clear drainage, if you feel very thirsty or urinate more than usual (a sign of diabetes insipidus), or any other symptoms that concern you.

**Hypothyroidism**

Hypothyroidism occurs primarily in women over 50 years old. If hypothyroidism occurs in an infant, severe problems with growth and development occur. This is why all babies born in the United States are tested for hypothyroidism at birth.

**Pathophysiology**

Primary hypothyroidism occurs when the thyroid gland fails to produce enough TH even though enough thyroid-stimulating hormone (TSH) is being secreted by the pituitary gland. The pituitary responds to the low level of TH by producing more TSH. Secondary hypothyroidism is caused by low levels of TSH, which fail to stimulate release of TH. Tertiary hypothyroidism results from inadequate release of thyrotropin-releasing hormone (TRH), secreted by the hypothalamus. Most cases of hypothyroidism are primary (Table 39.3).

Because thyroid hormones are responsible for metabolism, low levels of these hormones result in a slowed metabolic rate, which causes many of the characteristic symptoms of hypothyroidism.

**Etiology**

Primary hypothyroidism may be a result of a congenital defect, inflammation of the thyroid gland, or iodine deficiency. Hashimoto’s thyroiditis is an autoimmune disorder that eventually destroys thyroid tissue, leading to hypothyroidism. Secondary or tertiary hypothyroidism can be caused by a pituitary or hypothalamic lesion or by postpartum pituitary necrosis, a rare disorder in which the pituitary is destroyed after pregnancy and delivery. Treatment of hyperthyroidism, whether with medication or thyroidectomy, can lead to secondary hypothyroidism. Peripheral resistance to TH may also occur.

Signs and Symptoms

Manifestations are related to the reduced metabolic rate and include fatigue, weight gain, bradycardia, constipation, mental dullness, feeling cold, shortness of breath, decreased sweating, and dry skin and hair (“Patient Perspective” and Table 39.4). Heart failure may occur because of decreased pumping strength of the heart. Altered fat metabolism causes hyperlipidemia, which can lead to cardiovascular disease. In advanced disease, myxedema develops, which is a nonpitting edema of the face, hands, and feet.

Complications

If the metabolic rate drops so low that it becomes life threatening, the result is myxedema coma. This usually occurs in patients with long-standing, untreated hypothyroidism and can be triggered by stress such as infection, trauma, or exposure to cold. The patient becomes hypothermic, with a temperature less than 95°F (35°C), and has a decreased respiratory rate, depressed mental function, and lethargy. Blood glucose drops. Cardiac output drops, which in turn can reduce perfusion of kidneys. Death can occur as a result of heart or respiratory failure. If you note changes in mental status or vital signs, contact the registered nurse (RN) or health care provider (HCP) immediately. Treatment of myxedema coma involves intubation and mechanical ventilation. The patient is slowly rewarmed with blankets. IV levothyroxine (Synthroid) is given, and the underlying cause is treated.

Diagnostic Tests

The levels of T3 and T4 are low, and the level of TSH may be high or low, depending on the cause. If the pituitary is

myxedema: myx—mucus + edema—swelling

**Patient Perspective**

Mary

When I turned 40-something, I began to notice a few changes in my body. I seemed to be easily fatigued, but I attributed that to moving our family across country and all the adjustments that needed to be made. I also noticed weight gain, most notably around my waist. Again, I thought, “Well, I am 40-something,” but it seemed no matter how much I exercised and watched what I ate, I couldn’t lose weight. Worse, I was gaining! One day a friend of mine pointed out that I always seemed tired. Each time she called to do something, my reply was always the same, “I’d love to, but not today. I’m just so tired.”

Things started to get worse; I began losing hair by the handfuls each time I shampooed. It was so bad that every time I went to my hair stylist, she had to reassure me that I wasn’t going bald. However, my hair just didn’t seem as full as it once did. I began to notice dry skin (I thought it was just our hard water) and constipation (I thought I had irritable bowel syndrome). Finally, I went to the doctor for a physical, including laboratory tests, which included a TSH and free T4. The diagnosis came back: I had hypothyroidism and was started on Synthroid. I noticed the effect on my energy almost immediately. Now I am able to exercise effectively. I have lost nearly all the weight I gained, and my husband no longer complains about having to clean out the drain in our shower every time I wash my hair. I am thankful for the diagnosis and treatment because I feel like myself again.
functioning normally, TSH is elevated in an attempt to stimulate an increase in TH. Serum cholesterol and triglycerides are elevated. Antibodies are usually present in autoimmune disease.

**Therapeutic Measures**

Primary hypothyroidism is easily treated with oral thyroid replacement hormone. Most patients now take synthetic thyroid hormone (levothyroxine [Synthroid]). Doses are started low and are slowly increased to prevent symptoms of hyperthyroidism or cardiac complications.

**Nursing Process for the Patient With Hypothyroidism**

See the “Nursing Care Plan for the Patient With Hypothyroidism.”

### NURSING CARE PLAN for the Patient With Hypothyroidism

<table>
<thead>
<tr>
<th>Nursing Diagnosis:</th>
<th>Activity Intolerance related to fatigue</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Expected Outcomes:</strong></td>
<td>The patient will be able to tolerate activity as evidenced by (1) reports of lessening fatigue after treatment initiated and (2) the ability to carry out usual activities of daily living (ADLs).</td>
</tr>
<tr>
<td><strong>Evaluation of Outcomes:</strong></td>
<td>(1) Does patient report lessening fatigue? (2) Is patient able to carry out ADLs?</td>
</tr>
</tbody>
</table>

**Intervention**  
Assess level of fatigue. **Rationale** Assessment guides nursing care. **Evaluation** What is patient’s fatigue level?

**Intervention**  
Assist patient with self-care activities. **Rationale** Patients with fatigue may have difficulty carrying out activities independently. **Evaluation** Are patient’s self-care needs being met? Is assistance needed?

**Intervention**  
Allow for rest between activities. **Rationale** Rest periods will enable patient to conserve energy for activities. **Evaluation** Does patient state rest is adequate?

**Intervention**  
Slowly increase patient’s activities as medication begins to be effective. **Rationale** As thyroid replacement therapy becomes effective, patient’s fatigue will subside. **Evaluation** Does patient tolerate increases in activity?

**GERIATRIC**

**Intervention**  
When getting older patients up, watch for orthostatic hypotension. **Rationale** Orthostatic hypotension is common in older adults and may cause falls. **Evaluation** Does patient’s blood pressure drop when changing positions?

<table>
<thead>
<tr>
<th>Nursing Diagnosis:</th>
<th>Constipation related to slowed gastrointestinal (GI) motility</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Expected Outcome:</strong></td>
<td>Constipation will be resolved as evidenced by soft, formed stool passed at patient’s pre-illness frequency.</td>
</tr>
<tr>
<td><strong>Evaluation of Outcome:</strong></td>
<td>Are bowels movements soft and formed?</td>
</tr>
</tbody>
</table>

**Intervention**  
Monitor and record bowel movements. **Rationale** A record helps determine if a problem exists. **Evaluation** Does record show a problem?

**Intervention**  
Help patient follow usual pre-illness pattern (e.g., after morning coffee). **Rationale** A schedule allows bowel movement to occur before stool becomes hard and dry. **Evaluation** Is patient able to identify and implement usual self-care for bowels?

**Intervention**  
Increase fluids to eight 8-ounce glasses of water daily if cardiovascular status is stable. **Rationale** Adequate fluid intake helps prevent hard, dry stools. **Evaluation** Does patient take adequate fluids?

**Intervention**  
Add fiber to diet: fresh fruit, vegetables, bran. **Rationale** Fiber helps increase the number of bowel movements. **Evaluation** Does patient tolerate fiber? Is it effective?

**Intervention**  
Encourage regular ambulation. **Rationale** Activity increases peristalsis. **Evaluation** Is patient able to ambulate or engage in other activity?
NURSING CARE PLAN for the Patient With Hypothyroidism—cont’d

**Intervention** Use bedside commode or bathroom rather than bedpan. **Rationale** The sitting position aids in evacuation. **Evaluation** Is sitting position effective?

**Intervention** Obtain physician order for stool softener if needed. **Rationale** Soft stools are passed more easily. **Evaluation** Is stool softener needed? Is it effective?

**Intervention** If stool is impacted, break up stool digitally and gently remove. **Rationale** Breaking up stool eases evacuation. **Evaluation** Is stool impacted? Is digital disimpaction effective?

**Intervention** Avoid use of enemas. **Rationale** Enemas can cause fluid and electrolyte imbalances and can damage mucosa. **Evaluation** Does patient understand need to avoid enemas?

**Nursing Diagnosis:** Risk for Impaired Skin Integrity related to dry skin, inactivity

**Expected Outcome:** The patient’s skin will remain intact as evidenced by soft moist skin without lesions

**Evaluation of Outcome:** Is skin soft, moist, and intact?

**Intervention** Assess skin daily for breakdown and risk for breakdown. **Rationale** Skin lesions are more effectively treated when identified early. **Evaluation** Is breakdown present? Is patient at risk?

**Intervention** Avoid use of soap on dry areas. Try bath oil. **Rationale** Soap is drying to skin. **Evaluation** Does use of bath oil help?

**Intervention** Use nondrying lotion following bath. **Rationale** Lotion helps trap moisture in skin. Some lotions contain alcohol, which is drying. **Evaluation** Does patient state relief with use of lotion?

**Intervention** Encourage/assist with position changes at least every 2 hours. **Rationale** Changing position enhances circulation to the skin, promoting healing and preventing breakdown. **Evaluation** Does patient change position at least every 2 hours? Are pressure areas prevented?

**Nursing Diagnosis:** Imbalanced Nutrition: More Than Body Requirements related to decreased metabolic rate

**Expected Outcomes:**
1. Nutrition will be balanced as evidenced by return to patient’s pre-illness weight.
2. The patient will verbalize understanding of dietary recommendations.

**Evaluation of Outcomes:**
1. Is patient approaching pre-illness weight? (2) Is patient able to explain dietary recommendations and a plan for implementation?

**Intervention** Weigh weekly and record. **Rationale** Weekly weights record progress without the frustration of daily fluctuations. **Evaluation** Is patient approaching ideal weight?

**Intervention** Consult dietitian for therapeutic diet until hypothyroidism is controlled. **Rationale** The dietitian can provide food choices for gradual weight loss if necessary. **Evaluation** Does patient verbalize understanding of and ability to follow diet?

**Intervention** Encourage regular exercise within limits of fatigue. **Rationale** Exercise promotes weight control. **Evaluation** Does patient verbalize understanding of and ability to follow exercise plan?

**Intervention** Counsel patient that weight should normalize once hypothyroidism is controlled. **Rationale** Thyroid replacement hormone increases the metabolic rate, allowing return to normal weight. **Evaluation** Does patient verbalize understanding of instruction?

**GERIATRIC**

**Intervention** Allow patient to help determine acceptable diet modifications. **Rationale** Older patients may have long-standing dietary habits that are hard to change. **Evaluation** Is patient satisfied with weight loss plan?
**Patient Education**

Instruct the patient in the importance of consistent use of thyroid replacement medication and regular blood tests to monitor TSH. The patient needs to be aware that too much TH will cause symptoms of hyperthyroidism. Such symptoms should be reported to the physician immediately. In addition, if the patient is experiencing mental status changes, discuss the need to avoid driving or operating machinery until symptoms are resolved.

---

**Hyperthyroidism**

Hyperthyroidism is most often diagnosed in women. Graves’ disease, which is one cause of hyperthyroidism, is more common in young women. Multinodular goiter is more common in older women.

**Pathophysiology**

Hyperthyroidism results in excessive amounts of circulating TH (thyrotoxicosis). Primary hyperthyroidism occurs when a problem within the thyroid gland causes excess hormone release. Secondary hyperthyroidism occurs because of excess TSH release from the pituitary, causing overstimulation of the thyroid gland; tertiary hyperthyroidism is caused by excess TRH from the hypothalamus. A high level of TH increases the metabolic rate. It also increases the number of beta-adrenergic receptor sites in the body, which enhances the activity of epinephrine and norepinephrine. The resulting fight-or-flight response is the cause of many of the symptoms of hyperthyroidism.

**Etiology**

A variety of disorders can cause hyperthyroidism. Graves’ disease is the most common cause; it is an autoimmune disorder in which thyroid-stimulating antibodies cause the thyroid gland to make too much TH.

Other causes include thyroid nodules that secrete excess thyroid hormone (multinodular goiter and toxic adenoma), inflammation of the thyroid (thyroiditis), or a thyroid tumor. A pituitary tumor can secrete excess TSH, which overstimulates the thyroid gland. Patients taking TH for hypothyroidism may take too much. Each of these problems can cause excess circulating TH and symptoms of hyperthyroidism.

Radiation exposure can predispose a patient to develop hyperthyroidism. Heredity may also play a role in autoimmune hyperthyroidism. Women who smoke nearly double their risk of Graves’ disease.

**Signs and Symptoms**

Many signs and symptoms are related to the hypermetabolic state, such as heat intolerance, increased appetite with weight loss, and increased frequency of bowel movements. Nervousness, tremor, tachycardia, and palpitations are caused by the increase in sympathetic nervous system activity and may be more common in younger patients. Heart failure can occur because of tachycardia and the resulting inefficient pumping of the heart. See additional signs and symptoms in Table 39.4.

If treatment is not begun, the patient can become manic or psychotic. Additional signs that occur only with Graves’ disease include thickening of the skin on the anterior legs and exophthalmos (bulging of the eyes; Fig. 39.4) caused by swelling of the tissues behind the eyes. Other eye changes include photophobia and blurred or double vision.

Older adult patients may not have the typical signs and symptoms of hyperthyroidism, so be especially alert for this. These patients may present with heart failure, atrial fibrillation, fatigue, apathy, and depression.
Complications

THYROTOXIC CRISIS. Thyrotoxic crisis (sometimes called thyroid storm) is a severe hyperthyroid state that can occur in hyperthyroid people who are untreated or who develop another illness or stressor. It may also occur after thyroid surgery in patients who have been inadequately prepared with antithyroid medication. Thyrotoxic crisis can result in death in as little as 2 hours if untreated. Symptoms include tachycardia, high fever, hypertension (with eventual heart failure and hypotension), dehydration, restlessness, and delirium or coma.

If thyrotoxic crisis occurs, treatment is first directed toward relieving the life-threatening symptoms. Acetaminophen is given for the fever. Aspirin is avoided because it binds with the same serum protein as T4, freeing additional T4 into the circulation. IV fluids and a cooling blanket may be ordered to cool the patient. A beta-adrenergic blocker such as propranolol is given for tachycardia and symptom control. Oxygen is administered and the head of the bed is elevated because the high metabolic rate requires more oxygen. Once symptoms are controlled and the patient is safe, the underlying thyroid problem is treated.

HYPOTHYROIDISM. Another complication of hyperthyroidism can be hypothyroidism. This can occur as a result of long-term disease or as a result of treatment. Patients with a history of hyperthyroidism should be monitored for recurrent hypothyroidism or the onset of hypothyroidism.

Diagnostic Tests

Serum levels of T3 and T4 are elevated. TSH is low in primary hyperthyroidism or high if the cause is pituitary. A radioactive iodine uptake test or a thyroid scan can be done to determine hyperactivity of the gland or to locate a nodule or tumor. The thyroid gland may be enlarged; palpation of the thyroid in a patient suspected to be hyperthyroid should only be performed by a physician or an advanced practice nurse.

TSI (thyroid-stimulating immunoglobulin) is present in Graves’ disease.

Therapeutic Measures

Several medications can be used to treat hyperthyroidism. Propylthiouracil and methimazole (Tapazole) inhibit the synthesis of TH, but they may take several months to be effective and must be continued for 12 to 18 months. Propranolol (Inderal) is a beta-blocking medication that relieves the sympathetic nervous system symptoms. High doses of oral iodine suppress the release of thyroid hormone. Calcium and vitamin D are given to protect bones.

Radioactive iodine (¹³¹I or RAI) may be used to destroy a portion of the thyroid gland. The patient takes one oral dose of RAI. Dietary iodine normally goes to the thyroid gland, where it is used to make TH. When RAI is given, the radioactivity destroys some of the cells that make TH.

Sometimes medications or radioactive iodine alone control hyperthyroidism. If this does not occur, surgery is planned. If surgery is the treatment chosen, antithyroid medications are given to calm the thyroid before surger. They help slow the heart rate and reduce other symptoms, making surgery safer. Iodine also reduces the vascularity of the thyroid gland, decreasing the risk of bleeding during surgery. Adequate preparation of the patient is important because a euthyroid state helps prevent a postoperative thyrotoxic crisis.

Thyroidectomy can be done with a traditional, open approach, or with newer minimally invasive techniques that use a combination of a tiny incision and an endoscope. Patients can usually go home the same day and have a faster recovery time with minimally invasive surgery. The surgeon may choose to leave some of the thyroid gland intact, to continue to secrete some hormone. Following surgery, the patient will likely be hypothyroid and will require thyroid replacement hormone (levothyroxine [Synthroid]). Nursing care of the patient undergoing a thyroidectomy is discussed later in this chapter.

If vision is impaired from exophthalmos, surgical orbital decompression can be done. Current endoscopic techniques have made this a safer option than in the past.

Nursing Process for the Patient With Hyperthyroidism

DATA COLLECTION. Monitor the patient with hyperthyroidism closely until normal thyroid activity is restored. Assess vital signs and lung sounds and report changes to the RN or HCP. Assess level of anxiety and ability to cope with symptoms. Monitor weight, bowel function, and ability to sleep. Assess eyes for risk for injury caused by exophthalmos, and note degree of muscle weakness. Never palpate the thyroid gland of a patient with hyperthyroidism because palpation can stimulate release of thyroid hormone and precipitate a thyrotoxic crisis.

• WORD • BUILDING •

euthyroid: eu—normal, healthy + thyroid
NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.

Hyperthermia related to hypermetabolic state

**Expected Outcome:** The patient’s body temperature will be within normal limits.
- Monitor temperature. Temperature may be elevated due to hypermetabolic state.
- Administer acetaminophen as ordered (avoid aspirin) to reduce temperature. Aspirin can cause an increase in circulating thyroid hormone.
- Apply cooling blanket as ordered. External cooling may be needed if acetaminophen is not effective.
- If a cooling blanket is needed, set it to 1 to 2 degrees below the current temperature, and wrap the extremities with towels to prevent shivering, which can further increase temperature.
- Offer fluids to replace fluids lost through diaphoresis.

Diarrhea related to increase in peristalsis

**Expected Outcome:** The patient will maintain fluid and electrolyte balance.
- Provide a low-fiber diet. Fiber can increase peristalsis and stools.
- Provide small, frequent meals of bland foods (bananas, rice, applesauce) that are less likely to worsen diarrhea.
- Monitor electrolytes, especially sodium and potassium. Diarrhea can cause electrolyte loss.
- Monitor for dehydration. Diarrhea causes fluid loss.
- Keep skin clean and dry; apply barrier cream to protect skin from injury from stool.

Imbalanced Nutrition: Less Than Body Requirements related to increased metabolism

**Expected Outcome:** The patient will have balanced nutrition as evidenced by stable weight in proportion to height.
- Determine healthy weight for height, so that the expected outcome is realistic for the patient.
- Monitor weight weekly to make sure interventions are working.
- Consult dietician for high-calorie diet and supplements to meet caloric requirements.

Disturbed Sleep Pattern related to sympathetic stimulation

**Expected Outcome:** The patient will have improved sleep as evidenced by stating feeling rested upon awakening.
- Provide a quiet, restful environment to help the patient to fall asleep.
- Ask the patient if music or earplugs are desired to mask environmental noise.
- Administer propranolol or sedative as ordered to reduce sympathetic stimulation and calm patient.

Anxiety related to sympathetic stimulation

**Expected Outcome:** The patient will experience reduced anxiety as evidenced by patient statement that anxiety is controlled.
- Provide the patient with accurate information about the disorder and treatment, and explain that proper treatment will correct symptoms. Fear of the unknown can produce anxiety.
- Administer propranolol or anxiolytic agent as ordered to reduce sympathetic stimulation and calm patient.
- Offer massage, music, or other relaxation techniques preferred by the patient. These may promote relaxation.

Risk for Injury related to hypermetabolic state and bone and eye involvement

**Expected Outcome:** The patient will remain safe and without injury.
- Report changes in vital signs to RN or physician. Prompt treatment can reduce complications.
- Encourage all patients with Grave’s disease to stop smoking if they are smokers. Smoking is a risk factor for exophthalmos.
- Administer lubricating saline eye drops as ordered to protect eyes from drying.
- Advise use of dark, tight-fitting glasses to protect eyes from light and injury.
- Gently tape eyes shut with nonallergic tape for sleeping. Exophthalmos may prevent the patient from fully closing the eyes.
- Elevate the head of the bed to reduce edema behind the eyes.
- Provide a low-sodium diet. This may decrease edema behind the eyes.
- Teach patient to notify the physician immediately if eye pain or vision changes occur. These can be signs of pressure from edema on optic nerve, which can cause permanent damage if not corrected.
- Protect from injury and falls. Reduced bone density increases risk for fractures.

PATIENT EDUCATION. Teach the patient about the disease and symptoms of hyperthyroidism or hypothyroidism to report. Also teach the patient how to take medications and the importance of routine follow-up laboratory testing.

EVALUATION. If the plan of care is effective, the patient will remain free from complications and injury. Vital signs will be within normal limits. Diarrhea will be controlled, and complications of diarrhea such as skin breakdown and dehydration avoided. The patient’s weight should remain stable. The patient should report that he or she is rested on awakening and that anxiety is controlled.

Nursing Care of the Patient Receiving Radioactive Iodine

If radioactive iodine is used, it is usually given orally in one dose. If the dose is high, such as for the patient with thyroid cancer, the patient is hospitalized. Patients receiving lower doses may be treated as outpatients. You should limit time spent with the patient and maintain a safe distance when providing direct care (see Chapter 11). Pregnant caregivers should avoid caring for patients receiving radioactive iodine. Urine, vomitus, and other body secretions are contaminated and should be disposed of according to hospital policy. Flush
the goiter is removed, the gland usually returns to normal size.

Goiter
Pathophysiology and Etiology

Enlargement of the thyroid gland is called a goiter. The thyroid gland may enlarge in response to increased TSH levels, or sometimes in response to the autoimmune process that occurs in Graves’ disease. TSH is elevated in response to low TH, iodine deficiency, pregnancy, or viral, genetic, or other conditions. When a goiter is caused by iodine deficiency or other environmental factors, it is called an endemic goiter.

Some foods and medications are goitrogens. These substances interfere with the body’s use of iodine and include such foods as turnips, cabbage, broccoli, horseradish, cauliflower, and carrots (“Nutrition Notes”). Some goitrogenic medications include propylthiouracil, sulfonamides, lithium, and salicylates (aspirin).

A goiter can be associated with a hyperthyroid, hypothyroid, or euthyroid state. Goiter that occurs with hyperthyroidism is sometimes called a toxic goiter. Once the cause of the goiter is removed, the gland usually returns to normal size.

Signs and Symptoms

The thyroid gland is enlarged, and swelling may be apparent at the base of the neck (Fig. 39.5). Alternatively, the gland may enlarge posteriorly, which can interfere with swallowing or breathing. The patient may have a full sensation in the neck. Symptoms of hypothyroidism or hyperthyroidism may be present.

Diagnostic Tests

Serum TSH, T3, and T4 levels are measured to determine thyroid function. Ultrasound or a thyroid scan may be done to determine the cause or evaluate the size of the gland.

Nursing Care

Be careful to assess the effect of the goiter on breathing and swallowing. Stridor, a whistling sound, may be heard if the airway is obstructed. Stridor is an ominous sign and should be reported to the HCP immediately. If the patient experiences difficulty swallowing, notify the physician and collaborate.
with the dietitian to provide soft foods that are easy to swallow. A swallowing study might be ordered, which can assist a speech pathologist or other expert to make specific recommendations for safe swallowing.

Cancer of the Thyroid Gland

Although thyroid cancer is rare, it is the most common cancer of the endocrine system. Women are affected more often than men. Most tumors of the thyroid gland are not malignant. See Chapter 11 for cancer pathophysiology.

Etiology

Thyroid hyperplasia can lead to thyroid cancer. Other causes include exposure to radiation ("Cultural Considerations"), iodine deficiency, and prolonged exposure to goitrogens. The tendency to develop some forms of thyroid cancer is inherited.

Signs and Symptoms

A hard, painless nodule may be palpable on the thyroid gland. Difficulty breathing or swallowing, persistent cough, or changes in the voice may occur if the tumor is near the esophagus and trachea. Most patients with cancer of the thyroid have normal TH levels.

Diagnostic Tests

A thyroid scan shows a "cold" nodule. This is because malignant tumors of the thyroid do not take up the radioactive iodine administered for the scan. A "hot" nodule indicates a benign tumor. A fine-needle aspiration biopsy confirms the diagnosis.

Therapeutic Measures

A partial or total thyroidectomy may be done. Chemotherapy, radioactive iodine therapy, or external beam radiation may also be used, alone or following surgery.

Nursing Care

Nursing care is determined by the symptoms the patient is experiencing. See Chapter 11 for care of the patient with cancer.

Nursing Process for the Patient Undergoing Thyroidectomy

Patients may undergo thyroidectomy for cancer of the thyroid, hyperthyroidism, or a goiter that is causing dyspnea or dysphagia. See Chapter 12 for general care of a patient having surgery.

A total thyroidectomy is usually performed if cancer is present. After a total thyroidectomy, lifelong replacement hormone must be taken. A subtotal (partial) thyroidectomy might be done for hyperthyroidism, leaving a portion of the thyroid gland to continue to secrete TH.

Preoperative Care

Before undergoing a thyroidectomy, the patient should be in a euthyroid state to avoid complications during and after surgery. This is accomplished with the use of antithyroid medication such as methimazole (Tapazole). A saturated solution of potassium iodide may also be administered to decrease the size and vascularity of the gland, reducing the risk of bleeding during surgery.

Cultural Considerations

Because of the Chernobyl nuclear disaster in Russia in 1986, Russian immigrants are at exceptionally high risk for developing pituitary, thyroid, and parathyroid disorders and cancers. The proximity of Estonia, Latvia, Lithuania, Poland, and other Eastern European countries to Russia places immigrants and long-term visitors from these countries at risk as well. The nurse needs to be alert for endocrine disorders among these populations and assist patients to arrange genetic counseling for those who desire it.
Perform a baseline assessment of vital signs and voice quality, so you can compare findings postoperatively. Explain what the patient can expect before, during, and after surgery. Preoperative teaching should include how to perform gentle range-of-motion exercises of the neck, how to support the neck during position changes, and how to use an incentive spirometer after surgery. See Chapter 12 for routine preoperative care.

**Postoperative Care**

**DATA COLLECTION.** Monitor vital signs, oxygen saturation, drain (if present), and dressing every 15 minutes initially, progressing to every 4 hours, as ordered. Decreased blood pressure with increased pulse should alert you to the possibility of shock related to blood loss. Tachycardia and fever, along with mental status changes, can indicate thyrotoxic crisis. Check the back of the neck for pooling of blood. Because of the location of the surgery, observe for signs of respiratory distress, including an increase in respiratory rate, dyspnea, or stridor. Ask the patient to speak to detect hoarseness of the voice, which can indicate trauma to the recurrent laryngeal nerve. Monitor the patient’s serum calcium levels and watch for evidence of tetany (discussed later in this chapter). Report abnormal findings to the RN or physician immediately.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

**Risk for Ineffective Airway Clearance related to edema at surgical site**

**EXPECTED OUTCOME:** The patient will maintain a clear airway as evidenced by easy breathing without stridor.

- Notify physician about respiratory distress immediately; keep a tracheostomy set at the bedside. *Although not common, a tracheostomy may be needed in an emergency if edema obstructs the airway.*
- Maintain patient in semi-Fowler’s position to help reduce edema and promote comfort.
- Monitor neck dressing. *If the dressing seems to get tighter, it may be a sign that the patient’s neck is swelling, which could impair the airway.*
- Use room humidifier or humidified oxygen to keep airways and secretions moist.
- Remind the patient to do coughing and deep-breathing exercises every hour. *This keeps the airway clear of secretions.*
- Have suction equipment available in case patient is unable to cough up secretions effectively.
- Encourage the patient to use the incentive spirometer to assist with deep breathing.
- Assess the patient’s swallowing and gag reflexes before offering clear liquids to guard against aspiration.

**Risk for Injury (tetany, thyrotoxic crisis related to surgical procedure**

**EXPECTED OUTCOME:** Complications will be recognized and treated quickly.

- Monitor patient for muscle spasms or numbness or tingling around the mouth, and report immediately if they occur. *These are symptoms of tetany that must be treated immediately. Tetany is most likely to occur 24 to 72 hours postoperatively.*
- Monitor vital signs often, and report changes immediately. *Elevated vital signs may be signs of thyrotoxic crisis, which is most likely to occur up to 18 hours postoperatively.*

**Acute Pain related to surgical procedure**

**EXPECTED OUTCOME:** The patient’s pain will be controlled as evidenced by patient stating pain rating is acceptable.

- Administer acetaminophen or opioids as ordered. Avoid aspirin products. *Aspirin binds to the same protein as thyroid hormone and can precipitate a thyrotoxic crisis.*
- Use pillows or sandbags to support the patient’s head. *Unexpected movement may be painful.*

**Risk for Ineffective Self Health Management related to knowledge deficit**

**EXPECTED OUTCOME:** The patient will be able to effectively manage self-care needs as evidenced by (1) verbalizing understanding of follow-up care, (2) weight stabilizes at appropriate weight for height, and (3) TH levels are within normal limits.

- Teach the patient to do gentle range-of-motion exercises, avoiding hyperextension of the neck, which can cause strain on the incision line. *Avoidance of neck movement due to pain can result in contracture.*
- Consult dietitian to assist the patient with potential dietary changes needed following surgery. *With correction of metabolic alterations, dietary needs may be significantly altered.*
- Teach the patient the importance of follow-up care to avoid complications:
  - How to administer replacement hormone if ordered.
  - How to change the dressing and to report bleeding or signs of infection at the site.
  - Importance of immediately reporting unusual irritability, fever, palpitations, or signs of tetany.
  - Importance of follow-up lab work for thyroid function and medication adjustment.

**EVALUATION.** If the plan has been effective, complications caused by surgery will not occur or will be recognized and reported early. Pain will be prevented or controlled, and the patient will demonstrate understanding of postoperative self-care.

**Complications**

**THYROTOXIC CRISIS.** Thyrotoxic crisis can result from manipulation of the thyroid gland during surgery, with the subsequent release of large amounts of TH. This is a rare complication because the use of antithyroid drugs before surgery has become routine. For more information on thyrotoxic crisis, see the section on hyperthyroidism earlier in this chapter.

**TETANY.** Tetany is caused by low calcium levels and is characterized by tingling in the fingers and perioral area (around the mouth), muscle spasms, twitching, and cardiac dysrhythmias.
Muscle spasms in the larynx can lead to respiratory obstruction. Watch carefully for symptoms of tetany and report them immediately if they occur because if the problem is not recognized quickly, death can result.

Tetany can occur if the parathyroid glands are accidentally removed during thyroid surgery. Because of the proximity of the parathyroid glands to the thyroid, it is sometimes difficult for the surgeon to avoid them. In the absence of parathyroid hormone (PTH), serum calcium levels drop and tetany results. IV calcium gluconate is given to treat acute tetany.

**DISORDERS OF THE PARATHYROID GLANDS**

Recall that the parathyroid glands secrete PTH in response to low serum calcium levels. PTH raises serum calcium levels by promoting calcium movement from bones to blood, increasing absorption of dietary calcium, and increasing resorption of calcium by the kidneys. Decreased PTH activity is called hypoparathyroidism. Increased PTH activity is called hyperparathyroidism.

**Hypoparathyroidism**

*Pathophysiology*

A decrease in PTH causes a decrease in bone resorption of calcium, a decrease in calcium absorption by the GI tract, and decreased resorption in the kidneys. This means that calcium stays in the bones instead of being moved into the blood, and more calcium is excreted from the body. The result is a decreased serum calcium level, called hypocalcemia. As calcium levels fall, phosphate levels rise.

*Etiology*

The most common causes of hypoparathyroidism are heredity and the accidental removal of the parathyroid glands during thyroidectomy or other neck surgeries. Hypoparathyroidism also occurs following purposeful removal of the parathyroid glands for hyperparathyroidism or cancer. Another cause is hypomagnesemia, which impairs secretion of PTH. Hypomagnesemia can occur with chronic alcoholism or certain nutritional problems.

**Signs and Symptoms**

Calcium plays an important role in nerve cell stability. Hypocalcemia causes neuromuscular irritability. In acute cases, tetany can occur, with numbness and tingling of the fingers and perioral area, muscle spasms, and twitching (Table 39.5). Positive Chvostek’s and Trousseau’s signs are early indications of tetany. See Figures 6.4 and 6.5 in Chapter 6 for illustrations of these tests.

Chronic hypocalcemia can lead to lethargy; calcifications in the brain, leading to psychosis; cataracts; and convulsions. Bone changes may be evident on x-ray examination. Electrocardiogram (ECG) changes, and heart failure can develop because of the importance of calcium to cardiac function. Death can result from laryngospasm if treatment is not effective.

**Diagnostic Tests**

Laboratory studies show decreased serum calcium and PTH levels and increased serum phosphorus. An ECG is done to evaluate cardiac function. Radiographs show bone changes.

**Therapeutic Measures**

Acute cases of hypoparathyroidism are treated with IV calcium gluconate. Long-term treatment includes a high-calcium diet (Box 39-2), with oral calcium and vitamin D supplements. Magnesium is given if hypomagnesemia is present.

**Nursing Process for the Patient With Hypoparathyroidism**

**DATA COLLECTION.** The patient at risk for hypoparathyroidism should be closely monitored for symptoms of tetany.

If you suspect tetany, check for Chvostek’s and Trousseau’s signs. Monitor respirations closely for stridor, a sign of laryngospasm.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

**Risk for Injury related to hypocalcemia and tetany**

**EXPECTED OUTCOME:** The patient will remain free from injury; signs of tetany will be recognized and treated quickly.

- Monitor patient for signs of tetany, and report immediately to RN or physician so that treatment can begin quickly.
- Make sure a tracheostomy set, endotracheal tube, and IV calcium are available for emergency use if laryngospasm occurs.
- Consult a dietitian for high-calcium diet teaching. The patient may need a lifelong high-calcium diet.
- Teach the patient about the importance of long-term diet and medication therapy and follow-up laboratory testing. The patient needs to understand self-care for follow-up at home.

**EVALUATION.** Injury is prevented through early recognition and reporting of signs and symptoms of tetany. The patient should be able to describe correct treatment and self-care measures for home.

**Hyperparathyroidism**

**Pathophysiology**

Overactivity of one or more of the parathyroid glands causes an increase in PTH, with a subsequent increase in the serum calcium level (hypercalcemia). This is achieved through movement of calcium out of the bones and into the blood, absorption in the small intestine, and reabsorption by the kidneys. PTH also promotes phosphorus excretion by the kidneys.

**Etiology**

Hyperparathyroidism is usually the result of hyperplasia or a benign tumor of the parathyroid glands, or it may be hereditary. Parathyroid cancer is rare. Secondary hyperparathyroidism occurs when the parathyroids secrete excessive PTH in response to low serum calcium levels. Serum calcium may be reduced in kidney disease because of the kidneys’ failure to activate vitamin D, which is necessary for absorption of calcium in the small intestine.

**Signs and Symptoms**

Signs and symptoms of hyperparathyroidism are caused primarily by the increase in serum calcium level, although many patients are asymptomatic. Symptoms include fatigue, depression, confusion, increased urination, anorexia, nausea, vomiting, kidney stones, and cardiac dysrhythmias. The increased serum calcium level also causes gastrin secretion, resulting in abdominal pain and peptic ulcers. Because calcium is being removed from bones, bone and joint pain and pathological fractures can occur. Severe hypercalcemia can result in coma and cardiac arrest.

**Diagnostic Tests**

Laboratory studies include serum calcium, phosphorus, and PTH levels. Radiographs or bone density testing may show decreased bone density. A 24-hour urine test might be used to test how much calcium is being excreted in the urine. Nuclear scanning or ultrasound may be used to help locate the parathyroid glands if surgical removal is planned.

**Therapeutic Measures**

In acute situations, IV normal saline is given to hydrate the patient and lower the calcium level by dilution; furosemide (Lasix) is given to increase renal excretion of calcium. Alendronate (Fosamax) or calcitonin may be given to prevent calcium release from bones. For longer-term care, the patient is monitored for bone changes and decline in renal function. Oral calcium and vitamin D supplements are prescribed. Estrogen therapy might be used in women, although side effects must be considered.

If hypercalcemia is severe or if the patient is at risk for bone or kidney complications, surgery to remove the diseased parathyroid glands (parathyroidectomy) is performed. If possible, some parathyroid tissue is left intact to continue to secrete PTH. Minimally invasive radio-guided parathyroidectomy can be done under local anesthesia through a small incision.

Preoperative and postoperative care is similar to that of the patient undergoing thyroid surgery, with special attention paid to calcium and PTH levels. The patient will likely continue to be on calcium and vitamin D supplements following surgery.

**Nursing Process for the Patient With Hyperparathyroidism**

**DATA COLLECTION.** Assess the patient for symptoms related to hypercalcemia, including muscle weakness, lethargy, bone pain, anorexia, nausea, vomiting, behavioral changes, and renal insufficiency. Monitor serum calcium levels as ordered.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.** Nursing diagnoses depend on assessment findings. Risk for injury usually takes priority.
Risk for Injury (fracture, complications of hypercalcemia) related to calcium imbalance

Expected Outcome: The patient will remain free from injury.

- Monitor patient for signs or symptoms of calcium imbalance and report promptly. Prompt treatment can prevent serious complications.
- Encourage oral fluids to prevent dehydration and kidney stones and help excrete calcium.
- Encourage strengthening and weight-bearing exercises to help keep calcium in the bones.
- Provide a safe environment for ambulation; assist the patient with ambulation if needed. A fall could result in fracture if bones are demineralized.
- Encourage smoking cessation. Smoking causes bone loss.
- Teach patient symptoms to report and use of long-term medications so that patient can manage self-care at home.

EVALUATION. If the plan is effective, symptoms of hypercalcemia will be recognized and reported quickly, and complications and injury will be prevented.

DISORDERS OF THE ADRENAL GLANDS

Adrenal disorders can involve the adrenal medulla or the adrenal cortex. A rare tumor of the adrenal medulla, called a pheochromocytoma, causes hypersecretion of epinephrine and norepinephrine. Hyposecretion of epinephrine is rare and generally causes no symptoms. Hypersecretion of cortisol from the adrenal cortex results in Cushing’s syndrome. Hypofunction of the adrenal cortex results in Addison’s disease.

Pheochromocytoma

Pathophysiology

A pheochromocytoma is a rare tumor that arises from the chromaffin cells of the adrenal medulla. Occasionally, a pheochromocytoma occurs outside the adrenal gland, in the chest or abdomen. The tumor autonomously secretes catecholamines (epinephrine and norepinephrine) in excessive amounts. Most pheochromocytomas are benign.

Etiology

The cause of most cases of pheochromocytoma is unknown. About one-third of cases are hereditary.

Signs and Symptoms

Because norepinephrine is the fight-or-flight hormone, patients with a pheochromocytoma have exaggerated fight-or-flight symptoms. These might be fairly constant or occur in sporadic “attacks.” Manifestations include hypertension, tachycardia (with heart rate greater than 100 beats per minute), palpitations, tremor, diaphoresis, feeling of apprehension, and severe pounding headache. Nausea and vomiting are occasionally present. Blood glucose may increase because catecholamines inhibit insulin release from the pancreas. Constipation may occur because catecholamines relax the bowel. The most prominent characteristic is intermittent unstable hypertension. Diastolic pressure may be greater than 115 mm Hg. If hypertension and tachycardia are not controlled, the patient is at risk for stroke, heart attack and failure, vision changes, seizures, psychosis, and organ damage. It is estimated that about 0.1% of cases of hypertension are caused by a pheochromocytoma.

Diagnostic Tests

Patients with a suspected pheochromocytoma will have a 24-hour urine test for metanephrines and vanillylmandelic acid (VMA). These are end products of catecholamine metabolism. A blood test for metanephrines may also be done. The patient should avoid caffeine and medications for 2 days before and during the test. Check institution policy for other dietary restrictions. If results are ele vated, a CT scan or an MRI is done to locate the tumor.

Therapeutic Measures

Treatment for pheochromocytoma is surgical removal of one or both adrenal glands. Newer laparoscopic techniques make surgery safer than in the past. The patient must be stabilized before surgery. Calcium channel blockers and alpha blockers are used to control acute hypertension. Beta-blocking medication may be added to block beta-adrenergic receptors in the heart and lungs, reducing other fight-or-flight symptoms.

After surgery, the patient is at risk for hypotension, hypertension, and hypoglycemia. Monitor vital signs and blood glucose and report variations from normal. If both adrenal glands have been entirely removed, the patient will require lifelong replacement hormones. (See section on adrenalectomy later in this chapter.)

Nursing Process for the Patient With Pheochromocytoma

DATA COLLECTION. Monitor vital signs frequently, and report elevations promptly.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.

Risk for Injury related to hypertensive crisis

Expected Outcome: The patient will be free from injury related to hypertension.

- Monitor vital signs and report elevated pulse and blood pressure promptly. Prompt treatment helps prevent complications.
- Approach the patient calmly and maintain a quiet environment. Stress may precipitate a hypertensive episode.
- Administer medications as ordered to control symptoms.
- Teach the patient how the medications will reduce symptoms, and the importance of avoiding foods and beverages containing caffeine, so that the patient can participate in self-care.

- WORD • BUILDING •
pheochromocytoma: pheo—dark + chromo—color + cyt—cell + oma—tumor
Adrenocortical Insufficiency/Addison’s Disease

Adrenocortical insufficiency (AI) is the insufficient production of the hormones of the adrenal cortex. Primary AI is called Addison’s disease.

Pathophysiology

AI is associated with reduced levels of cortisol, aldosterone, or both hormones. A deficiency in androgens may also exist. In primary disease, ACTH levels from the pituitary can be elevated in an attempt to stimulate the adrenal cortex to synthesize more hormone. In secondary disease, deficient ACTH fails to stimulate adrenal steroid synthesis. In most cases, the adrenal glands are atrophied, small, and misshapen and are unable to produce adequate amounts of hormone.

Etiology

Addison’s disease is thought to be autoimmune; that is, the gland destroys itself in response to conditions such as tuberculosis, fungal infection, infection related to acquired immunodeficiency syndrome (AIDS), or metastatic cancer. It can also be associated with other autoimmune diseases, such as Hashimoto’s thyroiditis. Bilateral adrenalectomy also results in AI.

Secondary AI may be caused by dysfunction of the pituitary or hypothalamus. In addition, prolonged use of corticosteroid drugs can depress ACTH and corticotropin-releasing hormone production, which in turn reduces steroid hormone production. A patient receiving long-term corticosteroid therapy is particularly at risk for AI if the drugs are abruptly discontinued. Because the pituitary has been suppressed for a prolonged period, it may take up to a year before ACTH is produced normally again.

Complications

If a patient is exposed to stress, such as infection, trauma, or psychological pressure, the body may be unable to respond normally with secretion of cortisol (our natural stress hormone), and an adrenal crisis can occur. Loss of large amounts of sodium and water and the resulting fluid volume deficit cause profound hypotension, dehydration, and tachycardia. Potassium retention can cause cardiac dysrhythmias. Hypoglycemia may be severe. Coma and death result if treatment is not initiated. Treatment of adrenal crisis involves rapidly restoring fluid volume and cortisol levels. IV fluids (containing glucose) and large doses of IV glucocorticoids are administered. Electrolytes are replaced as needed. The cause of the crisis should be identified and treated.

Diagnostic Tests

Serum and urine cortisol levels are measured. Blood glucose is low. Blood urea nitrogen (BUN) and hematocrit levels may appear to be elevated because of dehydration. Antibodies may be present in the blood in autoimmune disease. An ACTH stimulation test may help determine whether the adrenal glands are functioning. Serum sodium and potassium levels are monitored. A CT scan or an MRI may be done to evaluate the size of the adrenal glands or to locate a pituitary tumor in secondary disease.

Therapeutic Measures

Long-term treatment consists of replacement of glucocorticoids (hydrocortisone) and mineralocorticoids (fludrocortisone). Some patients also receive androgen therapy. Patients will need hormone replacement therapy for the rest of their lives. Hormones are given in divided doses, with two-thirds of the daily dose given in the morning and one-third in the evening to mimic the body’s own diurnal rhythm. Remember that steroid hormones are our natural stress hormones and so are naturally elevated during times of stress. Therefore, during times of stress or illness, doses need to be increased to two to three times normal. The patient may also be placed on a high-sodium diet. If the patient is ill and can’t tolerate oral medication, hormones must be injected.

Nursing Process for the Patient With Addison’s Disease

DATA COLLECTION. The patient with Addison’s disease should be assessed for understanding of and adherence to the treatment regimen. Monitor vital signs and daily weights or I&O to track fluid status. Monitor serum glucose levels and symptoms of hyperkalemia and hyponatremia. Report changes in mental status. If the patient is in crisis, monitor vital signs closely and report any signs of fluid volume deficit such as orthostatic hypotension or poor skin turgor to the HCP immediately.
NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.

**Risk for Deficient Fluid Volume related to deficient adrenal cortical hormones**

**EXPECTED OUTCOME:** The patient’s fluid volume will be stable as evidenced by stable weights and vital signs, and skin turgor within normal limits.

- Monitor vital signs, and report change promptly. 
  Hypotension and tachycardia indicate hypovolemia.
- Monitor fluid status and report changes promptly to prevent complications of fluid deficit.
- Administer steroid replacements as ordered to maintain fluid and electrolyte balance.

**Risk for Ineffective Self Health Management related to deficient knowledge about self-care of Addison’s disease**

**EXPECTED OUTCOME:** The patient will verbalize understanding of self-monitoring and self-medication at home.

- Assess patient’s understanding of his or her disease process and treatment. 
  Teaching should build on baseline knowledge.
- Teach the patient the importance of hormone replacement as ordered. 
  The patient who does not secrete endogenous adrenocortical hormones must rely on replacements for survival.
- Help the patient identify the causes and symptoms of stress, and explain the need to increase medication dosage during times of stress or illness according to the physician’s instructions. 
  Because these hormones are normally increased during times of stress, it is important that the patient understand how to increase the dose during stress to prevent adrenal crisis.
- Advise patient he or she may need to increase salt intake in hot weather because of fluid and salt losses.
- Recommend medical alert identification. 
  A patient in adrenal crisis may not be able to provide a medical history to emergency personnel, and identification can prevent delay of treatment.

- If ordered by the physician, teach the patient and significant other how to use an emergency intramuscular (IM) hydrocortisone injection kit. IM medication may be needed during stress or times when the patient is unable to take oral medications.

**EVALUATION.** If nursing care is effective, the patient’s fluid status will be stable, and the patient and family will be able to carry out proper self-care of Addison’s disease.

**Cushing’s Syndrome**

Cushing’s syndrome is caused by exposure to excess cortisol. This can occur because of an adrenal problem, a pituitary problem, or from treatment with exogenous corticosteroids. See Table 39.6 for a comparison of adrenal insufficiency and Cushing’s syndrome.

**Pathophysiology**

Recall that cortisol, aldosterone, and androgens are the three steroid hormones secreted by the adrenal cortex. Cortisol is essential for survival and is normally secreted in a diurnal rhythm, with levels increasing in the early morning. Secretion is increased during times of stress. In Cushing’s syndrome, cortisol is hypersecreted without regard to stress or time of day. When levels of cortisol are very high, effects related to excess aldosterone and androgens are also seen.

**LEARNING TIP**

An easy way to remember the hormones of the adrenal cortex is to think salt, sugar, and sex. Aldosterone promotes salt retention, cortisol affects sugar (carbohydrate) metabolism, and androgens are sex hormones.
**Etiology**

Cushing’s syndrome can be caused by the hypersecretion of ACTH by the pituitary. This is most often the result of a benign pituitary adenoma. Sometimes ACTH is produced by a tumor in the lungs or other organs. The high levels of ACTH cause adrenal hyperplasia, which in turn increases production and release of cortisol. A problem within the adrenal gland, such as an adrenal adenoma or carcinoma can also produce excess cortisol.

The most common cause of Cushing’s syndrome is prolonged use of glucocorticoid medication (e.g., prednisone) for chronic inflammatory disorders such as rheumatoid arthritis, chronic obstructive pulmonary disease, and Crohn’s disease. The use of smaller doses of glucocorticoids (in inhalers for asthma) or topical creams does not usually cause a problem.

**Signs and Symptoms**

Most signs and symptoms of Cushing’s syndrome are related to excess cortisol levels. Weight gain, central obesity with thin arms and legs, fat pads on the upper back (buffalo hump), and a round, moon-shaped face result from deposits of adipose tissue at these sites (Fig. 39.6).

Cortisol also causes insulin resistance and stimulates gluconeogenesis, which results in glucose intolerance. Some patients develop secondary diabetes mellitus (see Chapter 40). Muscle wasting and thin skin with purple striae occur as a result of cortisol’s catabolic effect on tissues. Catabolic effects on bone lead to osteoporosis, pathological fractures, and back pain from compression fractures of the vertebrae. Because cortisol has anti-inflammatory and immunosuppressive actions, the patient is at risk for infection. Hyperpigmentation of the skin may occur. About half of patients develop mental status changes, from irritability to psychosis (sometimes referred to as steroid psychosis). Sodium and water retention are related to the mineralocorticoid effect. As sodium is retained, potassium is lost in the urine, causing hypokalemia. (See Chapter 6 to review these electrolyte imbalances.) Androgen effects include acne, growth of facial hair, and amenorrhea in women.

**Diagnostic Tests**

Suspicion of Cushing’s syndrome may initially be based on a cushingoid appearance and history of taking steroid medication. Plasma and urine cortisol and plasma ACTH are measured. A 24-hour urine test for cortisol may be collected. Levels of cortisol in the saliva may also be measured. A dexamethasone suppression test may be done. Serum potassium is measured. Additional tests to locate the cause of excess endogenous cortisol may be done.

**Therapeutic Measures**

If a pituitary or ACTH-secreting tumor is present, surgical removal or radiation therapy to the pituitary gland may be employed. If the adrenals are the primary cause of the problem, radiation or removal of the adrenal gland or glands may be performed. Minimally invasive surgeries have made surgery much safer. Drugs such as ketoconazole can be used to block production of adrenal steroids.

If the cause of Cushing’s syndrome is administration of steroid medication, a lower dose, an every-other-day schedule, or once-a-day dosing in the morning may reduce side effects. Usually steroids are prescribed as a last resort for chronic disorders that are unresponsive to other treatment. The patient and HCP must weigh the risks and benefits of continuing the medication. The HCP may order a high-potassium, low-sodium, high-protein diet. Potassium supplements may be ordered. If the patient has high blood sugar, appropriate therapy for diabetes is instituted (see Chapter 40).

**Nursing Process for the Patient With Cushing’s Syndrome**

**DATA COLLECTION.** When caring for the patient with Cushing’s syndrome, assess the patient’s medication history.
Monitor vital signs and complications related to fluid and sodium excess. Auscultate the lungs for crackles, and assess extremities for edema. Assess skin integrity, and monitor capillary glucose as ordered by the physician. Watch for signs of infection.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

**Risk for Excess Fluid Volume related to sodium and water retention**

**EXPECTED OUTCOME:** The patient’s fluid volume will be stable as evidenced by stable daily weights.

- Monitor daily weights and report changes promptly to prevent complications related to fluid excess.
- Teach the patient ordered dietary modifications. A low-sodium, high-potassium diet may help keep electrolytes in balance.

**Risk for Impaired Skin Integrity (thin, fragile skin) related to protein breakdown**

**EXPECTED OUTCOME:** The patient’s skin will remain intact.

- Observe skin, and monitor for breakdown with every position change. Early recognition and treatment of a problem can prevent further breakdown.
- Assist patient to change positions at least every 2 hours to prevent pressure ulcers.
- Use a lift sheet to move patient in bed to prevent friction and shear.
- Avoid harsh soaps and hot water. These can dry skin and increase risk for injury.
- Use moisturizing cream to keep skin from drying.
- Secure IVs and dressings without tape whenever possible. Removal of tape can tear fragile skin.
- Consider a specialty pressure-reducing mattress if the patient is very thin or unable to move to reduce the risk of pressure ulcer.
- Consult a dietitian if nutritional status is poor. Poor nutrition further increases risk for skin breakdown and poor healing.

**Risk for Infection related to immune suppression**

**EXPECTED OUTCOME:** The patient will be free from infection as evidenced by a white blood cell (WBC) count and temperature within normal limits.

- Monitor patient for signs of infection and report promptly so appropriate treatment can be ordered.
- Use good hand hygiene before and after patient care. Hand washing is important in reducing exposure to pathogens.
- Instruct the patient in good hand washing and in the importance of avoiding others who are ill. A patient with an impaired immune system is more likely to contract illness from others.
- Consult a dietitian if nutritional status is poor. Poor nutrition further impairs immune function.

**Risk for Unstable Blood Glucose Level related to impaired glucose tolerance**

**EXPECTED OUTCOME:** The patient’s blood glucose level will remain within normal limits.

- Encourage flu and pneumonia vaccinations to help prevent illness in event of exposure.

**Risk for Infection related to immune suppression**

**EXPECTED OUTCOME:** The patient’s blood glucose level will remain within normal limits.

- If glucose intolerance occurs, be prepared to administer insulin because oral hypoglycemics are not usually effective.
- Refer the patient and family to diabetes education classes because diabetes is a complex disease that requires knowledge of self-care.
- See Chapter 40 for care of the patient with diabetes.

**Disturbed Body Image related to cushingoid appearance**

**EXPECTED OUTCOME:** The patient will express feelings of acceptance of self.

- Approach patient with an attitude of acceptance and caring to help develop trusting nurse–patient relationship.
- Provide an opportunity for patient to verbalize feelings. Expressing feelings may help reduce anxiety.

**EVALUATION.** If care has been effective, complications of fluid overload will be recognized and treated early. The patient will have intact skin and be free from signs of infection. The patient will demonstrate skill in self-care of diabetes if indicated and will verbalize acceptance of self despite changes in appearance.

**Nursing Care of the Patient Undergoing Adrenalectomy**

**Preoperative Care**

Monitor the patient for electrolyte imbalance and hyperglycemia. Abnormalities must be corrected before surgery. To prevent adrenal crisis, glucocorticoids are administered because removal of the adrenals causes a sudden drop in adrenal hormones. Prepare the patient for adrenalectomy or hypophysectomy, depending on which surgery will be performed.

**Postoperative Care**

See care of the patient under going hypophysectomy earlier in this chapter. Following adrenalectomy, the patient receives routine postoperative care. In addition, the patient is closely monitored for changes in fluid and electrolyte balance and adrenal crisis. Patients who undergo bilateral adrenalectomy must take replacement glucocorticoid and mineralocorticoid hormones for the remainder of their life. If only one adrenal gland is removed, the remaining gland should eventually produce enough hormone to enable the patient to discontinue replacement hormone.

See Table 39.7 for a summary of endocrine disorders and Table 39.8 for a summary of medications used for endocrine disorders.

</table>
Mrs. Tercini is a 62-year-old woman admitted to your unit in Addisonian crisis. She is lethargic, with a blood pressure of 86/58 mm Hg, pulse 112, and respirations 18. While interviewing her daughter, you learn that Mrs. Tercini has a history of Cushing’s syndrome treated with bilateral adrenalectomy 25 years ago. She has been taking 150 mcg fludrocortisone (Florinef) and 200 mg hydrocortisone daily ever since. Three days ago she developed the flu.

1. Why is an adrenalectomy done to treat Cushing’s syndrome?

2. What is the most effective schedule for Mrs. Tercini’s medication?

3. What might have precipitated this Addisonian crisis?

4. Why is Mrs. Tercini’s blood pressure low?

5. How could this crisis have been prevented?

6. Fludrocortisone is available as 0.1-mg tablets. How many should you administer?

Suggested answers are at the end of the chapter.

Mrs. Jackson

1. Assess mental status and level of consciousness. Assess edema, lung sounds, and vital signs. Check intake and output during the past 2 days. Check recent lab work to see if her serum sodium is low. You also check a book on the unit and recall that anesthetics are possible causes of SIADH. Opioids, which Mrs. Jackson is likely taking after surgery, can also cause confusion.

2. Her weight gain is most likely caused by fluid retention, which can be a result of heart failure or SIADH, among other things.

3. Notify the registered nurse of your findings and suspicions. Be prepared to place Mrs. Jackson on a fluid restriction. Reassure her son that the physician is being notified of the changes he noted.

4. Remember “a pint’s a pound.” A pint is 2 cups for 480 mL.

\[
\begin{align*}
6 \text{ pounds} & \quad 480 \text{ mL} \\
1 \text{ pound} & \quad 2880 \text{ mL or almost 3 L}
\end{align*}
\]

Adoption

The children’s growth hormone secretion was probably suppressed because of psychosocial stress. Once they felt secure in a loving environment, growth hormone levels returned to normal.

Mrs. Maino

1. Mrs. Maino’s TSH is elevated because her pituitary gland is working overtime to try to stimulate the underactive thyroid gland.

2. Mrs. Maino’s metabolism has been slow, so she has been burning fewer calories. When she starts on thyroid replacement hormone, her metabolic rate will return to normal, and she will need more calories. Intake of calories should be balanced with the possible need for weight loss.

3. If Mrs. Maino receives too much thyroid hormone, she will have symptoms of hyperthyroidism, including an increased pulse rate. She should know how to check her pulse and to call her HCP if it is elevated.

4. The nurse, HCP, and dietitian are essential. A physical therapist may be helpful if mobilization and exercise recommendations are needed. A social worker or discharge planner can help with discharge needs.

Mrs. Tercini

1. Cushing’s syndrome is caused by too much cortisol. The adrenal cortex is responsible for secreting cortisol.

2. Mrs. Tercini should take two-thirds of her daily dose of hydrocortisone and fludrocortisone in the morning and one-third in the evening, or as ordered. This most closely mimics the body’s natural corticosteroid secretion.

3. The flu probably triggered this crisis. Illness is a stressor, and normally the body secretes steroids during stress. Because Mrs. Tercini’s body is unable to produce steroids, she experiences symptoms of hypoadrenalism during stressful times.

4. Mrs. Tercini’s blood pressure is low because she has insufficient circulating mineralocorticoids. Without aldosterone, sodium and water are lost and blood pressure drops.

5. Mrs. Tercini should have taken extra medication when she became ill. Her HCP should provide guidelines for dosing during stress and illness.

Chapter 39  Nursing Care of Patients With Endocrine Disorders

**REVIEW QUESTIONS**

1. Which assessment finding in a patient who has just returned from having a thyroidectomy should be immediately reported to the HCP?
   1. Neck discomfort
   2. Sore throat
   3. Tingling fingertips
   4. Sleepiness

2. A patient with SIADH asks the nurse why he has gained 10 pounds. Which response is best?
   1. “SIADH causes an increase in appetite. As soon as you are effectively treated, the weight should drop back to normal for you.”
   2. “You are retaining a lot of sodium and potassium, and that causes you to gain water weight.”
   3. “You have too much of a hormone in your system that causes you to retain water. The extra 10 pounds is likely water weight.”
   4. “Your kidneys are not working correctly, so they can’t get rid of extra water from your system.”

3. Which assessment finding should the nurse expect to see in the patient with uncontrolled diabetes insipidus?
   Select all that apply.
   1. Edema
   2. Polyuria
   3. Heat intolerance
   4. Diarrhea
   5. Polydipsia
   6. Dehydration

4. Which of the following instructions should the nurse provide to the patient who is being discharged after a thyroidectomy?
   1. “You must take your thyroid replacement every day just as the physician prescribed.”
   2. “You must weigh yourself daily and report any gain or loss of more than 1 pound.”
   3. “You will need to return to the physician’s office for a weekly blood pressure check.”
   4. “You will need to restrict your sodium and potassium intake.”

5. Which of the following nursing assessments is most important in the patient with hyperthyroidism and risk for thyrotoxic crisis?
   1. Intake and output
   2. Breath sounds
   3. Bowel sounds
   4. Vital signs

6. Which action by the nurse is most important following hypophysectomy?
   1. Performing a routine neurologic assessment
   2. Encouraging the patient to cough and deep breathe
   3. Monitoring for tracheal edema
   4. Assisting with use of an incentive spirometer

7. Which of the following statements by the patient with hypothyroidism indicates to the nurse that the plan of care has been effective?
   1. “I feel so much better now that my energy is returning.”
   2. “I’m really glad the diarrhea has stopped.”
   3. “I’m so glad I won’t have to take medication for very long.”
   4. “My fingers aren’t tingling anymore.”

Answers can be found in Appendix C.
KEY TERMS

diabetes mellitus (DYE-ah-BEE-tis mel-EYE-tus)
endogenous (en-DAW-jen-us)

glycosuria (GLY-kos-YOO-ree-ah)
hyperglycemia (HY-per-glye-SEE-mee-ah)
hypoglycemia (HY-poh-glye-SEE-mee-ah)
ketoacidosis (KEE-toh-as-ih-DOH-sis)
Kussmaul’s respirations (KOOS-mahlz RESS-per-AH-shuns)
nephropathy (neh-FROP-uh-thee)
neuropathy (nee-ROH-puh-thee)
nocturia (nok-TYOO-ree-ah)
polydipsia (PAH-lee-DIP-see-ah)
polyphagia (PAW-lee-FAY-je-ah)
polyuria (PAH-lee-YOO-ree-ah)
postprandial (POHST-PRAN-dee-uhl)
preprandial (PREE-PRAN-dee-uhl)
retinopathy (RET-in-NAW-puh-thee)

LEARNING OUTCOMES

1. Explain the pathophysiologies of type 1 and type 2 diabetes mellitus.
2. Identify risk factors for type 1 and type 2 diabetes mellitus.
3. Describe the signs and symptoms of diabetes mellitus.
4. Describe causes, signs and symptoms, and treatment of high and low blood glucose levels.
5. Discuss how diabetes increases risk of complications such as heart disease, blindness, and kidney failure.
6. Identify diagnostic tests used to diagnose and monitor diabetes mellitus and its complications.
7. Identify therapeutic measures to help patients with diabetes control blood glucose levels.
8. Differentiate the action of insulin and oral hypoglycemic agents in lowering blood glucose levels.
10. List measures to increase the safety of the patient with diabetes who is undergoing surgery.
**DIABETES MELLITUS**

**Diabetes mellitus** (be careful not to confuse this with diabetes insipidus) is a group of metabolic diseases in which defects in insulin secretion or action result in elevated blood glucose (hyperglycemia). According to the 2012 Centers for Disease Control and Prevention (CDC) data, approximately 29.1 million people or 9.3% of the population in the United States have diabetes mellitus. Approximately 8.1 million people have diabetes and don’t know it. Another 79 million have prediabetes. The direct and indirect cost (such as lost work time) of diabetes in the United States is about $245 billion per year. The incidence of diabetes mellitus varies by race and ethnicity. In the United States, Hispanic, African American, Native American, and Asian American populations have higher rates of diabetes than non-Hispanic white ethnic groups (CDC, 2012).

Diabetes is a serious disease that can cause complications such as blindness, kidney failure, heart attacks, and strokes. It is a leading cause of lower limb amputations in the United States. With good education and self-care, patients with diabetes can prevent or delay these complications and lead full, productive lives. Nurses play a major role in helping patients learn to care for themselves effectively.

**Pathophysiology**

Body tissues, and the cells that compose them, use glucose for energy. Glucose is a simple sugar provided by the foods we eat. When carbohydrates are eaten, they are digested into sugars, including glucose, which is then absorbed into the bloodstream. Carbohydrates provide most of the glucose used by the body; proteins and fats can indirectly provide smaller amounts of glucose. Glucose is able to enter the cells only with the help of insulin, a hormone produced by the beta cells in the islets of Langerhans of the pancreas (Fig. 40.1). When insulin comes in contact with the cell membrane, it combines with a receptor that allows activation of special glucose transporters in the membrane. By helping glucose enter the body’s cells, insulin lowers the glucose level in the blood. Insulin also helps the body store excess glucose in the liver in the form of glycogen.

Another hormone, glucagon, is produced by the alpha cells in the islets of Langerhans. Glucagon raises the blood glucose when needed by releasing stored glucose from the liver and muscles. Insulin and glucagon work together to keep the blood glucose at a constant level.

Diabetes results from deficient production of insulin by the beta cells in the pancreas, or from inability of the body’s cells to use insulin. When glucose is unable to enter body cells, it stays in the bloodstream; hyperglycemia results, and the cells are denied their energy source. Abnormal glucagon secretion may also play a role in type 2 diabetes. See Fig. 40.1.

**Types and Causes**

**Type 1 Diabetes Mellitus**

Type 1 diabetes (formerly called juvenile diabetes mellitus, insulin-dependent diabetes mellitus, or IDDM) is caused by destruction of the beta cells in the islets of Langerhans of the pancreas. When the beta cells are destroyed, they are unable to produce insulin. Insulin must then be injected for the body to use food for energy. See “Patient Perspective” for Dave’s story about having type 1 diabetes. Only about 5% of people with diabetes have type 1 diabetes.

**WORD • BUILDING •**

**diabetes mellitus:** diabetes—passing through + mellitus—sweet

**hyperglycemia:** hyper—excessive + glyc—glucose + emia—in the blood

---

**Patient Perspective**

**Dave**

I was diagnosed with type 1 diabetes mellitus at age 3 years. I remember being left in a children’s ward of the hospital with the nurses (who were nurses) in their habits and looking into the parking lot as my parents got in the car and drove away. I remember the fear and horror of being left alone. Later, I remember my doctor teaching my mother and me about the diet and monitoring my urine for glucose and ketones. This was all we had in those days (the early 1960s). I was supposed to test my urine before meals and at bedtime, just like we monitor blood glucose today. Every time I saw my doctor, he would review and change my treatment based on the results. Insulin then was extracted from pig and cow cadavers.

I remember my life being pretty normal except at holidays. When my brothers and sisters were getting Halloween candy and Christmas candy canes, I felt odd and left out. My mom was really tough and observant, and I had to be sneaky to get away with stealing a treat or two left momentarily unobserved by those around me. I was thrilled when sugarless candy became available around age 10 or so and I could have my own candies to hoard for myself.

Hypoglycemic reactions were always a trauma-filled event at our house. They came at unexpected times, and my mom sometimes blamed herself. I can honestly say that my mom deserves more credit than I have ever given her for my good fortune with my diabetes. She did not have glucometers, glycohemoglobin tests, or even diabetes specialists and educators; she just had the desire of a mother who did everything she could to make sure I had and did everything right as far as she knew.

In my late teens I took everything my doctor and my mom had done for me and trashed them. I lived with reckless abandon: I did what I wanted, ate what I wanted, and didn’t even think about the disease I lived with until I was about 30. I worked hard those years in construction, and the physical activity probably delayed the complications that might otherwise have occurred.
It is believed that the pancreas may attack itself following certain viral infections or administration of certain drugs. This is called an autoimmune response. Almost 90% of patients newly diagnosed with type 1 diabetes have islet cell antibodies in their blood. These antibodies might be present for years before actual symptoms of diabetes develop. About 10% of people with type 1 diabetes cases also have a genetic predisposition to its development. The patient with type 1 diabetes is most often young and thin and is prone to develop ketoacidosis when blood glucose is elevated. Diabetic ketoacidosis is discussed later in this chapter. See Table 40.1 for a comparison of type 1 and type 2 diabetes. Research studies are ongoing to try to find ways to prevent type 1 diabetes once antibodies have been detected.

**Type 2 Diabetes Mellitus**

Ninety-five percent of people with diabetes have type 2 diabetes mellitus (formerly called adult-onset diabetes mellitus, non–insulin-dependent diabetes mellitus, or NIDDM). In type 2 diabetes mellitus, tissues are resistant to insulin. Insulin is still made by the pancreas but in inadequate amounts. Sometimes the amount of insulin is normal or even high, but because the tissues are resistant to it, hyperglycemia results. As the disease advances, the pancreas eventually wears out, and insulin production decreases. When this occurs, the patient will likely require insulin injections. Simply using insulin, however, does not make the person a type 1 diabetic. He or she is a type 2 diabetic who needs insulin to control the blood glucose level.

---

Heredity is responsible for up to 90% of cases of type 2 diabetes. Obesity is also a major contributing factor. Often the patient with a new diagnosis of type 2 diabetes is obese, relates a family history of diabetes, and has had a recent life stressor such as the death of a family member, illness, or loss of a job.

### TABLE 40.1 COMPARISON OF TYPE 1 AND TYPE 2 DIABETES

Heredity is responsible for up to 90% of cases of type 2 diabetes. Obesity is also a major contributing factor. Often the patient with a new diagnosis of type 2 diabetes is obese, relates a family history of diabetes, and has had a recent life stressor such as the death of a family member, illness, or loss of a job.

**SELF-CARE TIP**

Drink more water! Type 2 diabetes has been linked to drinking sweetened drinks. Now, research has also linked type 2 diabetes with consumption of diet drinks sweetened with artificial sweeteners. Water, unsweetened teas, and sparkling waters are healthier choices.

### TYPE 2 DIABETES IN YOUTH.

More and more children and adolescents are developing type 2 diabetes, which in the past only occurred in adults. This is related to increasing obesity and decreasing activity levels in children today. Earlier onset of diabetes increases the risk of early complications, including death from cardiovascular disease.

### Gestational Diabetes

Gestational diabetes mellitus (GDM) occurs in 2% to 10% of pregnancies, especially in women with risk factors for type 2 diabetes. The extra metabolic demands of pregnancy trigger the onset of diabetes. Blood glucose usually returns to normal after delivery, but the mother has a 35% to 60% risk of developing type 2 diabetes within 10 to 20 years (CDC, 2011). If the mother with GDM is overweight, she should be counseled that weight loss and exercise will decrease her risk of developing diabetes. Mothers with GDM require specialized care and should be referred to an expert in this area.

### Prediabetes

Prediabetes refers to blood glucose levels that are above normal but do not meet the criteria for diagnosing diabetes (Fig. 40.2). Prediabetes usually occurs before the onset of type 2 diabetes. It is diagnosed by evaluating fasting blood glucose levels, glucose tolerance tests (see tests of diabetes below), or HbA1c. Those with prediabetes may be able to prevent the onset of diabetes with weight loss and exercise.

### Other Types of Diabetes

Secondary diabetes can develop as a result of another chronic illness that damages the islet cells, such as pancreatitis or cystic fibrosis. Prolonged use of some drugs, such as steroid hormones, phenytoin (Dilantin), thiazide diuretics, and thyroid hormone, can also impair insulin action and raise blood glucose. Less common causes include pancreatic trauma and other endocrine disorders.
Metabolic Syndrome
Prediabetes has been linked to a condition called metabolic syndrome or cardiometabolic syndrome. According to the American Heart Association and the National Heart, Lung, and Blood Institute, metabolic syndrome is diagnosed when at least three of the following criteria are met (American Heart Association, 2011):

1. Central or abdominal obesity (measured by waist circumference):
   - Men—greater than 40 inches
   - Women—greater than 35 inches
2. Fasting blood triglycerides greater than or equal to 150 mg/dL
3. Blood HDL cholesterol:
   - Men—less than 40 mg/dL
   - Women—less than 50 mg/dL
4. Blood pressure greater than or equal to 130/85 mm Hg
5. Fasting glucose greater than or equal to 100 mg/dL

Other risk factors include physical inactivity, aging, hormonal imbalance, and genetic predisposition. Hispanic Americans are at higher risk than Caucasians. A major factor is the growing obesity epidemic in the United States.

Any patient who fits this profile should be monitored closely for the onset of type 2 diabetes and heart disease. Patients should be counseled on the importance of a diet low in saturated fats and cholesterol, weight loss, physical activity, and control of blood pressure and cholesterol levels.

Signs and Symptoms
Classic symptoms of diabetes mellitus include polydipsia (excessive thirst), polyuria (excessive urination), and polyphagia (excessive hunger). The large amount of glucose in the blood causes an increase in serum concentration, or osmolality. The renal tubules are unable to reabsorb all the excess glucose that is filtered by the glomeruli, and glycosuria results. Large amounts of body water are required to excrete this glucose, causing polyuria, nocturia (nighttime urination), and dehydration. The increased osmolality and dehydration cause polydipsia. Because glucose is unable to enter the cells, the cells starve, causing polyphagia. High blood glucose can also cause fatigue, blurred vision, abdominal pain, and headaches. Ketones (acidic byproducts of fat breakdown) can build up in the blood and urine of patients with type 1 diabetes or late in the course of type 2 diabetes (ketoacidosis).

LEARNING TIP
Remember the classic symptoms of diabetes with the Three Ps: polydipsia, polyuria, and polyphagia.

Diagnostic Tests
Fasting Plasma Glucose Level
Diagnosis of diabetes mellitus is based on plasma glucose levels measured by a laboratory. According to the American Diabetes Association (ADA, 2014), a normal plasma glucose level is less than 100 mg/dL. When the fasting plasma glucose (drawn after at least 8 hours without eating) is 126 mg/dL or greater, diabetes is diagnosed. A second test may be required if the first test is not clearly diagnostic. If the fasting plasma glucose is between 100 and 125 mg/dL, the patient has IFG and prediabetes.

Random Plasma Glucose
Sometimes it is not feasible to check a fasting plasma glucose. A random plasma glucose (RPG) is checked without regard to the last meal. Diabetes is diagnosed if the RPG is 200 mg/dL or greater, with symptoms of diabetes.

Oral Glucose Tolerance Test
Another test to diagnose diabetes is the oral glucose tolerance test (OGTT). An OGTT measures blood glucose at intervals after the patient drinks a concentrated carbohydrate drink. Diabetes is diagnosed when the blood glucose level is 200 mg/dL or greater after 2 hours. A result between 140 and 199 mg/dL at 2 hours leads to a diagnosis of impaired glucose tolerance and prediabetes.

Glycohemoglobin
The glycohemoglobin test (also called glycosylated hemoglobin, or HbA1c [hemoglobin A1C]) is used to gather baseline data and to monitor the progress of diabetes control. In 2009, the ADA also changed its guidelines to include the HbA1c as a diagnostic test for diabetes.

Glucose in the blood attaches to hemoglobin in the red blood cells, which live about 3 months. When the glucose that is attached to the hemoglobin is measured, it reflects the average blood glucose level for the previous 2 to 3 months. This is a helpful measurement when blood glucose levels fluctuate and a single measurement would be misleading. It also assists in determining the degree of effectiveness of a patient’s treatment plan. A normal HbA1c is 4% to 6%. An HbA1c of 6.5% or higher is diagnostic for diabetes. An HbA1c between 6% and 6.5% indicates high risk for developing diabetes (prediabetes).

Newer methods allow this test to be done in a physician’s office while the patient waits. See Table 40.2 for a general blood glucose levels based on HbA1c results.

Glycohemoglobin testing might be inaccurate in some people, such as those with anemia. These patients may instead be tested for glycated serum protein (also called fructosamine), which is a similar test that indicates glucose levels over a period of 1 to 2 weeks instead of 3 months.
Estimated Average Glucose

Some health care providers (HCPs) use a calculation to convert HbA1c results to estimated average glucose (eAG) numbers, which may be more meaningful to patients. The formula is:

\[28.7 \times \text{HbA1c} - 46.7 = \text{eAG}.\]

Here is an example for a patient whose HbA1c is 8.6:

\[28.7 \times 8.6 - 46.7 = 200.12, \text{ which can be rounded to } 200 \text{ mg/dL.}\]

Additional Tests

Because diabetes affects so many body systems, additional tests recommended for baseline data include a lipid profile, serum creatinine, and urine microalbumin levels to monitor kidney function, urinalysis, and electrocardiogram.

CRITICAL THINKING

Mr. McMillan

Mr. McMillan is a 50-year-old patient brought into the emergency department with extreme fatigue and dehydration. After the physician sees him, you ask Mr. McMillan some additional questions. Based on the patient’s answers, you request that the physician add a glucose level to the laboratory tests ordered. The result is 1400 mg/dL.

1. What questions would you ask Mr. McMillan if you suspected diabetes?
2. Why was Mr. McMillan fatigued?
3. Why was he dehydrated?

Source: American Diabetes Association (2014).

Prevention

Studies are ongoing to find ways prevent type 1 diabetes in people at risk. It is possible to prevent type 2 diabetes. Research studies have shown that patients at risk for type 2 diabetes, even those who already have impaired glucose tolerance or impaired fasting glucose (IFG), can prevent or delay the onset of diabetes with weight loss and regular exercise. On the basis of this research, the ADA (2014) recommends loss of 7% of body weight and moderate physical activity for 150 minutes per week. Use of the diabetes medication metformin can also help prevent diabetes in patients with prediabetes. Patients at risk should have their plasma glucose level checked regularly.

Therapeutic Measures

The only cure for diabetes is a pancreas (or islet cell) transplant. However, diabetes can be controlled. Treatment begins with diet and exercise. Insulin is added in patients with type 1 diabetes and insulin or oral hypoglycemic medication as needed in those with type 2 diabetes. Weight loss is essential for patients who have type 2 diabetes and are overweight or obese. Blood glucose monitoring and education are also important to good diabetes control.

To monitor the effectiveness of treatment, patients should have regular health care follow-up visits. See Box 40-1 for a summary of the diabetes goals and recommendations proposed by the ADA for 2014.

**Box 40-1 Summary of Diabetes Goals and Recommendations for Adults**

**Target levels:**

- **HbA1c**
  - Less than 7%
- **Preprandial capillary glucose**
  - 70–130 mg/dL
- **Peak postprandial capillary glucose**
  - Less than 180 mg/dL
- **Blood pressure**
  - Less than 140/80 mm Hg

Blood lipids should be measured every 1 to 2 years, depending on risk. Target levels are as follows:

- **Low-density lipoproteins**
  - Less than 100 mg/dL
- **Triglycerides**
  - Less than 150 mg/dL
- **High-density lipoproteins**
  - Greater than 40 mg/dL (men)
  - Greater than 50 mg/dL (women)

**General recommendations:**

- **Yearly flu vaccine for all patients age 6 months and older**
- **One lifetime pneumococcal vaccine for patients older than age 2 years, with revaccination for patients older than age 65 years if first vaccine was more than 5 years earlier**

Continued
Goals of Treatment

The ADA recommends that patients maintain a preprandial (premeal) plasma glucose level of 70 to 130 mg/dL, peak postprandial glucose less than 180 mg/dL, and glycohemoglobin level of less than 7% to prevent or delay complications of diabetes. Because of the risk for cardiovascular disease, they also recommend maintaining blood pressure of less than 140/80 mm Hg (ADA, 2014). All goals may be adjusted in individual circumstances. For example, the patient who is unable to feel symptoms of hypoglycemia (low blood glucose) might have a higher preprandial glucose goal to prevent undetected hypoglycemic episodes.

Medical Nutrition Therapy

The goal of medical nutrition therapy is to achieve and maintain blood glucose and lipid levels as near to normal as possible to prevent long-term complications. For some, especially those with type 2 diabetes, weight loss and cholesterol and blood pressure control may be additional goals of nutrition therapy.

Because the patient with diabetes has a limited amount of insulin, either endogenous (from within the body) or injected, it is important to eat an amount of food that will not exceed the insulin’s ability to carry it into the cells. This requires a meal plan that includes consistent amounts of carbohydrates, proteins, and fats each day. Because carbohydrates contribute most to the blood glucose level, it is important that the amount of carbohydrates consumed is consistent from one day to the next. If a patient eats a small amount of carbohydrate one day and a large amount the next, the blood glucose will fluctuate, leading to complications. It is possible to relax nutrition restrictions somewhat if the patient is willing to test blood glucose frequently at home and adjust treatment accordingly.

The ADA recommends a complete assessment by a specially trained dietician and an individualized nutrition therapy plan and teaching. The education of the patient with diabetes is a process that may take months and cannot be accomplished in a single visit or with a paper handout or referral to a website. Various meal plans are available, as shown in “Nutrition Notes.” Because diabetes increases the risk of high serum cholesterol and triglycerides, all plans limit fat intake.

* WORD * BUILDING *
preprandial: pre—before + prandial—meal
postprandial: post—after + prandial—meal
hypoglycemia: hypo—deficient + glyc—glucose + emia—in the blood
endogenous: endo—within + genous—to produce

Nutrition Notes

Diabetic Meal Plans

Nutrition is integral to the management of diabetes and oftentimes the most challenging aspect of treatment for patients. No single approach is suitable for everyone but should be individualized based on the patient’s health status and lifestyle, ability to learn, and willingness to change.

Overall goals and strategies differ by type of diabetes. In general:

• Patients with type 1 diabetes need to prevent wide swings in blood glucose levels through careful timing of meals and snacks in relation to insulin therapy and activity.

• Patients with type 2 diabetes use diet modifications with medication as needed to maintain near-normal glucose, blood pressure, and lipid levels and to lose weight as needed.

People with diabetes usually benefit from eating on a regular basis (every 4 to 5 hours while awake). Evidence has shown that the use of sucrose (table sugar) as part of the meal plan does not impair blood glucose control in individuals with diabetes.

A CDE can devise a meal plan based on the patient’s abilities, past dietary habits, and commitment. Several meal-planning approaches are described next.

Create Your Plate

The ADA has devised a simple method of meal planning that divides a plate into one half and two quarters. The plate is filled with nonstarchy vegetables. One quarter is filled with starchy foods, such as whole grains and starchy vegetables. The last quarter is used for meats and meat substitutes. Finally, a serving of fruit and an 8-ounce glass of nonfat or low-fat milk completes the meal (Fig. 40.3).

Examples of foods suitable for each section of the plate are provided at www.diabetes.org/food-and-fitness/food/planning-meals/create-your-plate/?loc=ff-diabetesmealplans.
Using Carbohydrate Counting

Because carbohydrate is the energy nutrient that has the greatest influence on blood glucose levels, the amount and timing of carbohydrate intake directly affect diabetes control. Only carbohydrates are counted with this system, but patients are counseled to eat about the same amount of protein each day and to choose low-fat foods. Reading labels is mandatory; some fat-free products are higher in carbohydrate than the items they replace.

Carbohydrate counting classifies all carbohydrates together, whether from starch, fruit, or milk (Table 40.3). This method offers more flexibility both in food choices within a day’s meal plan and in insulin dosage than other systems and may achieve better control of blood glucose.

Despite those advantages, carbohydrate counting may entail the following:

- Weighing and measuring food
- Keeping food records
- Monitoring blood glucose before and after eating
- Controlling body weight.

This system does not permit carbohydrate intake as desired. Patients should maintain their carbohydrate intake at the same level each day to keep blood glucose as close to normal as possible. Carbohydrate counting is frequently inaccurate and associated with higher daily blood glucose levels.

National Institutes of Health Diabetes Pyramid

The National Diabetes Information Clearinghouse at the National Institutes of Health has developed extensive instructional materials on diabetes management. A diabetes food pyramid illustrates food groups and sample foods, including desirable methods of preparation. Categories of caloric needs by sex, weight, and activity levels are correlated with numbers of servings from each food group that could be used by the diabetic educator to visualize a patient’s diet prescription. The site is not copyrighted, and reproduction of the printable sheets is encouraged. See http://diabetes.niddk.nih.gov/dm/pubs/eating_ez/#pyramid.

Exchange Lists

An exchange system is composed of six lists of foods (starch, vegetable, fruit, milk, meat, fat) plus a “free food” list. Foods in each list contain similar energy nutrients (carbohydrate, protein, and fat). For example, green peas are on the starch list rather than the vegetable list because they are closer in composition to a slice of bread than to green beans.

Individual food items within an exchange list are essentially equal to each other in nutrient composition and can thus be exchanged or swapped for each other. Exchanges were designed to be approximately equal in nutrients, not in volume; therefore, portion sizes vary widely. For instance, one fruit exchange is equal to 1 1/4 cup of whole strawberries but to only three dates.

To use this method correctly, for each meal, patients must choose the prescribed number of items from each appropriate list on their meal plan. A meal plan is a food guide that shows the number of choices or exchanges the patient should eat at each meal and snack, based on the total daily calories prescribed. Users of the exchange system should weigh or measure their portions several times per week to avoid portion inflation. For more information, see www.eatright.org/search.aspx?search=Exchange%20lists.

*Additional proteins and fats are added in moderate amounts but need not be counted. Each item selected is approximately 15 grams of carbohydrate or 1 carb exchange.
**Glycemic Index**

All carbohydrates are not metabolized identically. Foods containing equal amounts of carbohydrate affect blood glucose levels differently. The glycemic index is a classification of foods according to the speed and degree of change they produce in blood glucose levels. The standard is commonly set with glucose given a value of 100; other foods are then compared with glucose. For example, a sweet potato has a glycemic index of 54, and peanuts have a glycemic index of 14. The values are determined for the tested food only. Effects in a mixed meal may vary. Motivated patients have incorporated the glycemic index into the successful management of their disease.

**Reference**

Patients who use fat replacers (in foods such as fat-free baked goods or ice cream) should be aware that they still have food value and calories, so they cannot be considered “free” foods. Simple sugars, which may raise blood glucose more than complex carbohydrates (they have a higher glycemic index), are used less but are not prohibited as they were in the past. Sodium intake is limited in individuals with hypertension. In the past, protein was limited in patients with an y degree of kidney impairment; this is no longer recommended. Any meal plan should be chosen to fit the patient’s lifestyle and food preferences. Patient preferences based on ethnic background should also be considered (“Cultural Considerations”).

Many patients now use the carbohydrate counting method, which allows some degree of freedom for the patient who is able to learn to read labels and monitor carbohydrate intake (see Table 40.3). If the patient carefully counts carbohydrates, other foods do not need to be as tightly controlled, as long as general recommendations such as monitoring insulin and sodium intake are followed. The success of medical nutrition therapy is evaluated by monitoring glucose levels, HbA1c, lipids, weight, blood pressure, and kidney function.

**Exercise**

Exercise lowers blood glucose by improving the sensitivity of muscles to insulin, and the effects can last up to 48 hours. Exercise also improves blood lipid levels and circulation, which is important for the person with diabetes who already has an increased risk of cardiovascular disease. Patients are instructed to engage in moderate aerobic exercise at least 150 minutes per week, spread over at least 3 days of the week. Resistance exercise also improves insulin sensitivity and is recommended (ADA 2014).

Patients with complications of diabetes must be careful in their exercise choices. For example, a patient with retinopathy should not do anything that causes straining. (See “Long-Term Complications” later in this chapter.) A patient with neuropathy or foot problems should limit weight-bearing exercise. The HCP or an exercise physiologist should be consulted for an individualized exercise plan.

Persons with diabetes who take insulin or medications that increase insulin secretion should check their blood glucose before exercise and always carry a quick source of glucose when exercising in case the blood glucose drops too low. They should also be cautious about exercising at the time of day when their blood glucose is at its lowest point (i.e., when insulin or medication action is peaking) and to have a carbohydrate snack before exercising if blood glucose is less than 100 mg/dL.

Caution patients to avoid exercise if they have ketones in their blood or urine. This indicates that insufficient insulin is available and glycogen may be released during exercise, further increasing the serum glucose.

**Medication**

**INJECTED INSULIN.** The person with type 1 diabetes has no endogenous insulin and therefore must inject insulin daily. At this time, insulin cannot be taken by mouth because it is a protein and is therefore digested, although oral and other forms of insulin are being developed. Insulin is typically given subcutaneously; fast-acting insulin may be ordered via the intramuscular or intravenous (IV) route in urgent situations. Several types of insulin are available with various schedules by which they may be given. The type and schedule are determined by the HCP in collaboration with the patient, based on the patient’s lifestyle and willingness to spend time...
on injections. In general, more frequent injections lead to better glucose control.

**Site Rotation.** Insulin injections should be given in a different subcutaneous site with each dose to avoid tissue injury. A sample rotation chart is shown in Fig. 40.4. Because each area absorbs insulin at a slightly different rate, it is advisable to use one area for a week, then move on to the next area. Within that area, each injection should be spaced at least 1 inch from the previous injection. Some experts recommend using primarily the torso (abdomen and buttocks) to provide more uniform absorption. Aspirating for blood before injection and rubbing the site after injection are not recommended with insulin injections.

**Insulin Pumps.** Patients who desire tighter control of blood glucose levels and a more flexible lifestyle may choose to use an insulin pump (Fig. 40.5). A pump delivers subcutaneous insulin via a tiny catheter continuously in small (basal) amounts. The catheter is placed in subcutaneous tissue and remains in place for 2 to 3 days. The patient can then add a bolus of insulin with the push of a button before meals or snacks. This provides insulin levels that are more normal, like those of a person without diabetes. A pump typically is worn on the abdomen or buttocks. Some models receive input from continuous glucose monitors.

**Insulin Sources.** Insulin is synthetically produced in a laboratory and is either identical to human insulin, or one or two amino acids different (called insulin analogs). In the past, insulin was derived from cows and pigs; this is no longer available in the United States but may be available from other countries. Be careful to check the source when preparing insulin for injection (especially if you work in home care, where patients could purchase their insulin online from another country) because insulins from different sources may act slightly differently. Some people may be allergic to beef or pork preparations or may refuse them based on cultural practices.

**Onset, Peak, and Duration.** Once insulin is injected, a period elapses before it begins to lower blood glucose. This time is called the *onset of action*. The *peak action* occurs when the insulin is working at its hardest and the blood glucose is at its lowest point. It is during this peak time that the patient is most at risk for an episode of low blood glucose. *Duration of action* is the length of time the insulin works before it is used up. Onset, peak, and duration are determined by whether the insulin is short, intermediate, or long acting (Table 40.4). It is important for the individual with diabetes and the nurse to be aware of the onset, peak, and duration of any insulin given. This assists in making decisions such as when to give insulin in relation to meals, when to exercise, and when to be alert to low blood glucose symptoms.

**Insulin Regimens.** In the past, most patients with diabetes used an injection of intermediate-acting insulin before breakfast and possibly a second injection before supper. Many patients are now choosing to take more frequent injections of short-acting insulin before meals or a combination of short- and long-acting insulins to achieve better, “tighter” control. These patients are often taught to adjust their insulin dose based on blood glucose level and the amount of carbohydrates eaten. Although patients who choose tight control have to be more cautious about risk for hypoglycemia, it can significantly reduce the risk of long-term complications.

One regimen that is becoming more common because it mimics normal insulin secretion is sometimes called *basal-bolus insulin*. This consists of an injection of a basal insulin (such as Lantus) once a day, often at bedtime, to provide a constant small amount of insulin in the bloodstream. Then an injection of very short-acting insulin (such as Humalog) is given before meals to mimic the extra insulin that is secreted normally with meals.

**Sliding-Scale Insulin.** Some patients receive varying doses of short-acting insulin before meals based on their blood glucose reading. An example of a sliding scale might read as follows: “BG <140, 0 units; BG 141–170, 2 units; BG 171–200, 4 units; >200 call HCP.” This is useful when the patient is ill and glucose levels are unstable, or when adjustments need to be made. However, routine use of sliding scale insulin is not recommended because although it corrects an already-high blood glucose, it is preferable to prevent hyperglycemia before it happens with routine insulin doses.
Mixing Insulins. When two insulins need to be given at the same time, they can often be mixed together to prevent having to give more than one injection. (See DavisPlus for procedure.) Preset mixtures of intermediate- and short-acting insulins are also available.

**PROBLEMS REQUIRING INSULIN ADJUSTMENT.** Two problems that can occur with glucose control are the Somogyi effect and the dawn phenomenon. The Somogyi effect may be at fault when the patient's blood glucose seems to be rising despite increasing insulin doses. If insulin levels are too high, the blood glucose may drop too low, stimulating release of counterregulatory hormones (epinephrine, glucagon, corticosteroids, growth hormone), which then elevate the blood glucose. The low glucose levels often occur during the night, and the patient may report night sweats or morning headaches. The high morning glucose is then interpreted as hyperglycemia, and the insulin dose may be further increased, compounding the problem.

The dawn phenomenon is thought to occur because of the natural release of growth hormone and cortisol during the early morning hours. This causes hyperglycemia on arising in the morning.

The patient might be asked to monitor blood glucose between 0200 and 0400 in addition to bedtime and morning testing to assess whether the Somogyi effect or the dawn phenomenon is occurring. Correction of the Somogyi effect involves reducing the insulin dose. The dawn phenomenon is treated with careful adjustment of meals and insulin so that insulin is peaking when the blood glucose is highest.

**ORAL HYPOGLYCEMIC MEDICATION.** The patient with type 2 diabetes may be able to control blood glucose levels with medical nutrition therapy and exercise alone. If needed, oral hypoglycemic medication or insulin will also be prescribed. Oral hypoglycemic agents are not insulin pills but work in ways such as stimulating the pancreas to produce more insulin or making the tissues more sensitive to insulin. Because most oral hypoglycemic agents depend on at least a partially functioning pancreas, most are not useful for patients with type 1 diabetes. See Table 40.5 for a list of commonly used oral hypoglycemic agents and their mechanisms of action.

Most oral hypoglycemic agents should be administered before meals. Care should be taken to prevent passage of more than 30 minutes between medication administration and the meal because this may result in a hypoglycemic episode. Some must be taken with, rather than before, meals. Check individual drugs for specific timing.

If the blood glucose level is not controlled with an oral hypoglycemic agent, insulin may be needed for the person with type 2 diabetes. This does not mean the person has type 1 diabetes. Insulin may be needed to control blood glucose but unlike in the person with type 1 diabetes, insulin is not needed to sustain life.

**CRITICAL THINKING**

**Mrs. Evans**

Mrs. Evans is a 78-year-old woman with type 2 diabetes who resides in the long-term care facility at which you work. She is on 42 units of Lantus insulin every evening and 10 units of Humalog insulin before each meal.

1. What time should you administer her Lantus insulin? If she eats her meals at 0800, 1200, and 1700, when should her Humalog insulin be administered?

2. At what time of day should she be alert for symptoms of low blood glucose?

3. What could happen if Mrs. Evans feels ill and misses her lunch?

4. Mrs. Evans receives an apple with her meal but cannot eat it because her dentures do not fit well. She is on an ADA Exchange List diet. What should you do?

Suggested answers are at the end of the chapter.

</tbody>
</table>
INCRETIN MIMETIC AGENTS. A newer group of medications are the incretin mimetics. These are injectable drugs that were first isolated in the saliva of the Gila monster, a poisonous lizard native to the United States and Mexico. An incretin mimetic mimics natural incretins in the body. Incretins are hormones secreted by the gastrointestinal (GI) tract that (1) stimulate insulin release and (2) reduce glucagon release in response to nutrients in the intestine. Examples of incretin mimetics include exenatide (Byetta or Bydureon) and liraglutide (Victoza). These drugs can work in conjunction with oral hypoglycemic agents and stimulate insulin secretion, lower production of glucagon, slow gastric emptying, and promote weight loss.

Another injectable drug, pramlintide (Symlin), is used with insulin. It is a synthetic analog of amylin, a naturally occurring hormone that reduces glucose levels following meals. It may also promote weight loss in individuals who are overweight. Patients using Symlin have an increased risk of hypoglycemia.

NATURAL REMEDIES. Many herbs and other natural remedies have been promoted for diabetes treatment. If your patient wishes to try a natural remedy, it is essential to encourage a conversation with his or her HCP first. See the evidence about cinnamon in the “Evidence-Based Practice” feature.

Self-Monitoring of Blood Glucose
The ability to test blood glucose levels at home has been a major advance in diabetes care. Blood glucose can be better controlled because of the availability of monitoring at any time, in any place. A variety of blood glucose monitors are on the market at reasonable prices; one example is shown in Fig. 40.6. Most of the cost involved in monitoring is in the test strips that must be used. Health insurance programs may cover this cost.

Self-monitoring of blood glucose is usually done before meals and at bedtime by the person on insulin who wants to maintain tight control of blood glucose. Patients using multiple insulin injections should check capillary plasma glucose before meals and snacks, occasionally postprandially, at bedtime, before exercise, when experiencing low blood glucose, and before critical activities such as driving (ADA, 2014). Less frequent schedules may be prescribed for patients who are unable or unwilling to test four times a day or for patients not on insulin.

New devices are available that continuously monitor glucose via a small catheter inserted into the abdomen. The device records the glucose level every 5 minutes on a monitor that is worn like a pager on a belt. It can be set to alarm if the blood glucose level drops too low.

The diabetes provider should be consulted for desirable blood glucose ranges because these may differ for each patient. The ADA recommends a preprandial goal of 70 to 130 mg/dL for most patients. Patients who are prone to hypoglycemia or small children or older adults may have higher goal ranges, such as 100 to 150 mg/dL. Lower blood glucose levels for these populations could increase the risk of hypoglycemia.

An important aspect of blood glucose monitoring is the interpretation of results. Monitoring is useless if the results are not used to improve blood glucose control. The patient should be instructed to keep a diary of blood glucose levels (Fig. 40.7). Some patients have computer software that graphs results. The patient may be taught by a diabetes educator to interpret the trends in the results, or the diary may be taken on a regular basis to the HCP for interpretation and adjustment of the treatment plan.

EVIDENCE-BASED PRACTICE

Clinical Question
Does cinnamon lower blood glucose in patients with diabetes?

Evidence
Ten research studies were reviewed, involving 577 subjects with diabetes. There was no evidence that cinnamon was better than placebo in lowering blood glucose or HbA1c.

Implications for Nursing Practice
Many patients look for natural remedies to replace or supplement prescribed therapies. It is important for nurses to encourage patients to find evidence to support their decisions, and to talk with their HCP before trying new treatments. They should never stop current treatment without consulting their HCP.

REFERENCE

FIGURE 40.6 OneTouch Ultra glucose monitor. Courtesy of LifeScan.
Urine also may be tested for glucose and for ketones. Urine glucose testing was done routinely before the development of self-monitoring of blood glucose. A variety of dipsticks and tape products are available for urine testing. Glucose in the urine makes the patient aware that the blood glucose is elevated, but the actual level is unknown. Most people have glucose in their urine when their blood glucose is more than about 180 mg/dL, although this can be highly variable in patients with diabetes. It is difficult to base treatment on urine glucose levels, and so routine urine testing for glucose is no longer recommended.

Urine should be tested for ketones during acute illness or stress, when blood glucose levels are elevated in ketosis-prone patients, or when symptoms of ketoacidosis are present (see later in this chapter). If ketones are present, the patient knows an insulin deficiency is present and should notify the physician. Patients with type 1 diabetes are most at risk for developing ketoacidosis; however, it is wise for the patient with type 2 diabetes to test for ketones if risk factors are present. See Table 40.6 for a review of diabetes symptoms, diagnosis, and treatment.

**Urine Glucose and Ketone Monitoring**

Urine glucose testing was done routinely before the development of self-monitoring of blood glucose. A variety of dipsticks and tape products are available for urine testing. Glucose in the urine makes the patient aware that the blood glucose is elevated, but the actual level is unknown. Most people have glucose in their urine when their blood glucose is more than about 180 mg/dL, although this can be highly variable in patients with diabetes. It is difficult to base treatment on urine glucose levels, and so routine urine testing for glucose is no longer recommended.

Urine should be tested for ketones during acute illness or stress, when blood glucose levels are elevated in ketosis-prone patients, or when symptoms of ketoacidosis are present (see later in this chapter). If ketones are present, the patient knows an insulin deficiency is present and should notify the physician. Patients with type 1 diabetes are most at risk for developing ketoacidosis; however, it is wise for the patient with type 2 diabetes to test for ketones if risk factors are present. See Table 40.6 for a review of diabetes symptoms, diagnosis, and treatment.

**Weight Loss**

Weight loss can help the patient with type 2 diabetes control blood glucose, blood pressure, and blood lipid levels. Weight loss can even help prevent the need for medication in some patients. In obese patients who have difficulty losing weight with usual measures, bariatric surgery may be considered. There are several bariatric surgeries that may be effective; see Chapter 33 for more information.

Transplant
If the patient is evaluated to be an appropriate candidate, a pancreas transplant may be considered. This is especially beneficial in the patient with kidney disease, who can receive both a kidney and pancreas transplant at the same time. Another promising treatment is the implantation of pancreatic islet cells.

Acute Complications of Diabetes
A person with diabetes is at risk for a variety of complications. Acute complications related to high and low blood glucose levels are treatable and can be prevented with appropriate care.

Hyperglycemia
When calories eaten exceed insulin available or glucose used, high blood glucose (hyperglycemia) occurs. A common cause of hyperglycemia is eating more than the meal plan prescribes. Another major cause is stress. Stress causes the release of counterregulatory hormones, including epinephrine, cortisol, growth hormone, and glucagon. These hormones all increase the blood glucose level. In a person without diabetes, this is an adaptive function. However, the patient with diabetes is unable to compensate for the increased blood glucose with increased insulin secretion, and hyperglycemia results.

Patients must be able to recognize signs and symptoms of high blood glucose levels and know what to do if they occur (Table 40.7). For many patients, these are similar to the symptoms they experienced when they were first diagnosed with diabetes. Chronic high blood glucose levels can lead to long-term complications (discussed later in this chapter).

Hypoglycemia
Low blood glucose, or hypoglycemia, occurs when there is not enough glucose available in relation to circulating insulin. This is sometimes referred to as an insulin reaction. Hypoglycemia is usually defined as a blood glucose level below 70 mg/dL, although patients may feel symptoms at higher or lower levels. Occasionally, symptoms occur as a result of a rapid drop in blood glucose, even though the actual glucose level is normal or high. Causes of hypoglycemia may include skipping a meal, exercising more than usual, or accidentally administering too much insulin. An occasional hypoglycemic episode, treated promptly, should not lead to chronic complications. Repeated or extremely low blood glucose levels can cause neurologic damage because there is not enough glucose for brain function. It is therefore important to teach patients and families how to prevent and treat low blood glucose (see Table 40.7).

Symptoms of hypoglycemia include hunger, sweating, pallor, tremor, palpitations, and headache. These symptoms are caused by activation of the sympathetic nervous system. As hypoglycemia progresses, the brain is deprived of glucose (called neuroglycopenia) and neurologic symptoms such as irritability, confusion, seizures, and coma may occur.

</tbody>
</table>
To treat low blood glucose, administer a “fast sugar”—15 to 20 grams of carbohydrate that will enter the bloodstream quickly (Box 40-2). If the patient is not alert or is unable to safely swallow, subcutaneous glucagon can be given by the registered nurse (RN). Recheck the blood glucose in 15 minutes. If it does not return to at least 70 mg/dL, repeat the procedure every 15 minutes until 70 mg/dL is reached—even if the patient is feeling better. Do not overtreat hypoglycemia with too much sugar because this may cause hyperglycemia and rebound hypoglycemia.

If you find someone with symptoms of altered blood glucose but are unable to identify whether it is high or low, do a blood glucose test. However, if the patient has neurologic symptoms, treat for low blood glucose immediately. The blood glucose may then be checked and further treatment provided as indicated.

Some older adult patients with poor autonomic nervous system function or patients taking beta-adrenergic blocking medication such as propranolol or atenolol (which block the sympathetic response) may not feel the symptoms of hypoglycemia. These patients should check glucose levels more often and keep the levels in a safe range to prevent hypoglycemic episodes.

All people with diabetes should be instructed to keep a fast sugar in their purse or pocket at all times. Fast sugars may also be stored in bedside tables, cars, and desks at work.

**Diabetic Ketoacidosis**

**PATHOPHYSIOLOGY.** Diabetic ketoacidosis (DKA) occurs when blood glucose levels become very high and insulin is deficient. This most commonly occurs in people with type 1 diabetes, but it may occur in type 2 diabetes when insulin deficiency exists, usually late in the disease process. DKA symptoms are often the reason a person with undiagnosed type 1 diabetes first seeks help. It may also be the result of stress or illness in a person with previously diagnosed type 1 (or rarely, type 2) diabetes. When there is insufficient insulin to allow glucose into cells, the cells starve. The body then breaks down fat to be used for energy. The fat breakdown releases an acid substance called ketones. As ketones build up in the blood, ketoacidosis occurs.

The body attempts to compensate for acidosis by deepening respirations to blow off excess carbon dioxide. Because carbon dioxide combines with water in the body to form carbonic acid, blowing off carbon dioxide is like blowing off acid. (See the section on metabolic acidosis in Chapter 6.) The deep, sighing respiratory pattern is called Kussmaul’s respirations. The expired air has a fruity odor caused by the ketones and may be mistaken for alcohol. Some nurses have likened the odor to Juicy Fruit® chewing gum.

With such high blood glucose and the accompanying polyuria, the body becomes dehydrated very quickly. Tachycardia, hypotension, and shock can result. Acidosis also causes potassium to leave the cells and accumulate in the blood (hyperkalemia). Potassium is then lost in large amounts in the urine, which can lead to hypokalemia. The combination of dehydration, potassium imbalance, and acidosis causes the patient to develop flulike symptoms, including abdominal pain and vomiting. The patient loses consciousness and death occurs if DKA is not treated. The mortality rate for DKA is about 2%.

**THERAPEUTIC MEASURES.** Treatment includes IV fluids, IV insulin, and blood glucose monitoring, often initially in an intensive care unit setting. Glucose is added to the IV when
the blood glucose drops to about 180 mg/dL to avoid hypoglycemia. Potassium should also be monitored closely because it is essential to have normal levels for cardiac function. Arterial blood gases help monitor acidosis. The cause of the DKA should be identified and treated.

Prevention of ketoadidosis involves careful monitoring of blood glucose levels at home. Teach at-risk patients to use a urine dipstick to check for ketones (Ketostix) if blood glucose is elevated. If ketones are present, the patient should drink water and recheck with the next urination. If ketones are still present, the physician should be notified. Instruct patients never to stop their insulin without a physician’s supervision.

**Hyperosmolar Hyperglycemic State**

**PATHOPHYSIOLOGY.** Hyperosmolar hyperglycemic state (HHS, also called hyperosmolar hyperglycemic nonketotic syndrome, or HHNK) occurs mainly in type 2 diabetes, when blood glucose levels are high and the patient has reduced fluid intake as a result of stress or illness. Because the person with type 2 diabetes has some insulin production, cells do not starve, and DKA usually does not occur. HHS occurs more often in older adults.

As blood glucose level rises (hyperglycemia), polyuria causes profound dehydration, producing the hyperosmolar (concentrated) state. Blood glucose may rise as high as 1500 mg/dL, and electrolyte imbalances occur. Because ketoacidosis is not present, the patient may not feel as physically ill as the patient with DKA and may delay seeking treatment. Symptoms of HHS develop slowly and include extreme thirst, lethargy, and mental confusion. Shock, coma, and death occur if it is left untreated. The mortality rate for HHS is between 10% and 20%.

**THERAPEUTIC MEASURES.** Treatment includes IV fluids and insulin, and glucose monitoring. Electrolytes are closely monitored. The cause of HHS should be identified and treated. HHS can be prevented with careful monitoring of glucose levels at home. Teach at-risk patients to use a urine dipstick to check for ketones (Ketostix) if blood glucose is elevated. If ketones are present, the patient should drink water and recheck with the next urination. If ketones are still present, the physician should be notified. Instruct patients never to stop their insulin without a physician’s supervision.

**NURSING CARE TIP**

Government insurers (Medicare and Medicaid) consider DKA, HHS, and hypoglycemic coma to be preventable problems and will no longer pay hospitals for the extra expense of caring for patients who develop these conditions after they are in the hospital. You can help control costs by being vigilant for early signs and symptoms of these complications and reporting them promptly. The website that lists additional hospital-acquired conditions is [www.cms.gov/HospitalAcqCond](http://www.cms.gov/HospitalAcqCond).

**Long-Term Complications**

Over time, chronic hyperglycemia causes a variety of serious complications in persons with diabetes. These involve the circulatory system, eyes, kidneys, skin, and nerves. Most of the complications involve either the large blood vessels in the body (macrovascular complications) or the tiny blood vessels, such as those in the eyes or kidneys (microvascular complications). The Diabetes Control and Complications Trial (DCCT), a large classic research study completed in 1993, showed that individuals with type 1 diabetes who maintain tight control of blood glucose experience fewer long-term microvascular complications than individuals who take traditional care of their diabetes (Diabetes Control and Complications Trial Research Group, 1993). Similarly, the United Kingdom Prospective Diabetes Study (UKPDS), completed in 1998, showed that individuals with type 2 diabetes who maintain an HbA1c below 7% can significantly reduce complications. In fact, for every percentage of decrease in HbA1c, there were 25% fewer deaths from diabetes-related complications (UK Prospective Diabetes Study Group, 1998). Unfortunately, tight control can be accompanied by an increased risk of hypoglycemia, and even tight control does not guarantee the prevention of all long-term complications.

**Macrovascular Complications**

**CIRCULATORY SYSTEM.** People with diabetes develop atherosclerosis and arteriosclerosis faster than the general population. They are more likely to have hypertension and elevated low-density lipoprotein cholesterol and triglyceride levels. High blood glucose can also affect platelet function, leading to increased clotting. These problems lead to a higher incidence of strokes, heart attacks, and poor circulation in the feet and legs. The risk of cardiovascular disease and strokes is two to four times more common in persons with diabetes than in the general population.

Control of blood glucose, blood pressure, and cholesterol levels is vital to help prevent these deadly complications. Patients should also avoid smoking, maintain normal weight, and exercise regularly. All patients should be evaluated by their HCP for treatment with aspirin or other antiplatelet medication, angiotensin-converting enzyme (ACE) inhibitor therapy, and statin therapy for control of blood lipids.

**Microvascular Complications**

**EYES.** Small blood vessels can become diseased, eventually leading to retinopathy in most patients with diabetes. Retinopathy involves damage to the tiny blood vessels that supply the eye. Small hemorrhages occur, which can cause blindness if not corrected. Diabetes is a leading cause of blindness in adults in the United States (CDC, 2014). Good control of blood glucose and blood pressure can reduce the risk of retinopathy. Newer laser surgery techniques may help improve vision after hemorrhages occur. Diabetes is also associated with a high incidence of cataracts. Patients with diabetes should have a yearly dilated eye examination.
KIDNEYS. Nephropathy is caused by damage to the tiny blood vessels in the kidneys. Up to 40% of patients with diabetes develop some degree of nephropathy. Native Americans, Hispanics, and African Americans have the highest risk. A primary risk factor for diabetic nephropathy is poor control of blood glucose. If nephropathy occurs, the kidneys are unable to remove waste products and excess fluid from the blood. Diabetes is the leading cause of end-stage renal (kidney) disease (ESRD) in the United States. When the kidneys have lost most of their function, patients may have their blood cleansed artificially by either hemodialysis or peritoneal dialysis (see Chapter 37). The only cure for ESRD is a kidney transplant.

Patients should be taught the importance of blood glucose control to prevent or delay kidney disease. ACE inhibitor and angiotensin receptor blocker (ARB) medications have been shown to slow the development of kidney problems in patients with diabetes. Patients who have both diabetes and hypertension should be placed on an ACE inhibitor or ARB. Routine urine tests are done to check for albumin in the urine. A trained renal dietitian should work with the patient and physician to determine the best diet for the patient.

Nerve Complications

Another complication of diabetes is neuropathy, which is damage to nerves as a result of chronic hyperglycemia. Neuropathy can cause numbness and pain in the extremities, erectile dysfunction (impotence) in men, sexual dysfunction in women, gastroparesis (delayed stomach emptying), and other problems. Unfortunately, pain caused by neuropathy is difficult to treat with traditional analgesics. Some antidepresant and anticonvulsant drugs may be helpful, and in some cases, local injections of anesthetics may be used. Anticonvulsant agents gabapentin (Neurontin) and pregabalin (Lyrica) reduce painful nerve impulses in individuals with nerve pain. Improved control of blood glucose levels may also help.

Infection

Persons with diabetes are prone to infection for several reasons. If injuries occur, healing may be slow because of impaired circulation. There may not be enough blood supply to heal the wound or fight an infection. For the same reason, it may be difficult for IV antibiotics to reach an infected site, and topical antibiotics may be preferable. In the presence of hyperglycemia, white blood cells (WBCs) become sluggish and ineffective, further reducing the body’s ability to fight infection.

The incidence of periodontal (gum) disease, caused by bacteria in plaque, is also increased in individuals with diabetes. Patients must be taught to maintain good oral hygiene and make regular visits to the dentist.

Foot Complications

The combination of macrovascular disease, neuropathy, and risk for infection makes patients with diabetes prone to foot problems. Consider the patient who has no feeling in his or her feet because of neuropathy. If the patient has a foot injury, it may not be felt right away. Vascular disease will prevent a good blood supply from preventing infection and promoting healing. If infection sets in, it is slow to resolve and may progress to necrosis and gangrene. Pressure points on the feet may also break down (Fig. 40.8). One woman had a Bic pen in her shoe all day and did not realize it! Neuropathy can also lead to deformities of the feet, further increasing the risk of injuries.

For these reasons, diabetes is the leading cause of nontraumatic amputation of the lower extremities in the United States. Teach patients to protect their feet at all times by wearing well-fitting shoes and by washing, drying, and inspecting their feet daily (Box 40-3). If any sores are noted, the patient should not delay in seeking treatment. During routine visits to the physician, teach the patient to be sure to remove shoes and socks so the feet can be thoroughly examined. The physician or diabetes specialist can test sensation in the feet with tiny filaments. Loss of protective sensation is an early risk factor for amputation, so any reduction in sensation is a warning sign that extra care must be taken.

* WORD BUILDING *

neuropathy: neuro—nervous system + pathy—illness
nephropathy: nephro—of the kidney + pathy—illness
gastroparesis: gastro—stomach + paresis—partial paralysis

be taken. A podiatrist (foot doctor) can be consulted if problems occur. Specialized wound treatment centers have new healing techniques that have prevented many amputations. (See DavisPlus for “Ethical Considerations.”)

**Box 40-3 Foot Care Tips**

- Wash and dry feet every day. Use warm (not hot) water to avoid burns.
- Apply lotion that does not contain alcohol, avoiding areas between toes.
- Inspect feet for sores or red areas daily (have a family member help if necessary).
- Report any abnormalities immediately.
- Wear leather shoes and white or light-colored cotton socks.
- Never go barefoot.
- Avoid garters and tight socks.
- Avoid crossing legs.
- Cut toenails to natural shape of nail—not into corners.
- See a podiatrist for calluses or problem toenails (avoid “bathroom surgery”).
- Have feet checked at least once a year, preferably three to four times a year, for loss of sensation.

**NURSING CARE TIP**

Encourage patients to wear white or light-colored socks. One woman did not know she had a wound on her foot till she saw blood coming through her white cotton socks.

**CRITICAL THINKING**

**Mr. Jones**

- Mr. Jones is a 54-year-old banker with type 2 diabetes admitted to your unit with a tiny red area on his right heel. His admitting blood glucose is 360 mg/dL. The lesion is so small you wonder what the fuss is about. While doing his assessment, you find that he wore a new pair of shoes to work all day about a month ago and has been avoiding seeing his physician about the resulting red area. He is placed on IV antibiotics, and within 3 days, the red area has broken open and has yellow drainage. He is sent home with topical antibiotics and crutches, to be followed by a visiting nurse. The wound takes 6 months to fully heal.

1. Why do you think crutches are necessary?
2. Why do you think the wound took so long to heal?
3. Why do you think the wound took so long to heal?
4. Why do you think topical antibiotics work better than IV antibiotics?
5. The nurse documents the following description of Mr. Jones’s wound: “Small red open area on heel, with yellow drainage on dressing.” What is wrong with this charting? How can you improve it?
6. What team members should be involved with Mr. Jones’s care?

Suggested answers are at the end of the chapter.

**Special Considerations for the Patient Undergoing Surgery**

Surgery is a stressor. The counterregulatory hormones released during stress cause the blood glucose to rise, even if the patient has been fasting. High blood glucose levels interfere with immune function and healing and can increase the patient’s risk for infection. Some research studies have shown that tight blood glucose control during hospitalization and surgery can significantly reduce complications. Other studies have shown that tight control increases the risk of hypoglycemia and death. In 2009, the ADA and American Association of Clinical Endocrinologists determined that glucose levels in critically ill hospitalized patients should be maintained between 140 and 180 mg/dL, preferably with the use of IV insulin (Moghissi et al, 2009). See the “Nursing Care Plan for the Patient With Diabetes Mellitus” for goals for patients who are not critically ill.

Check with the physician for actual insulin orders. Often patients are placed on IV infusions of glucose and insulin during and immediately after surgery, in place of longer-acting insulins. Monitor blood glucose levels every 2 to 4 hours or as ordered, and monitor carefully for signs and symptoms of hypoglycemia or hyperglycemia. If a patient uses a pump at home, check with a diabetes resource nurse to determine if the patient can continue to use it during hospitalization.

Patients who were not previously on insulin may be placed on insulin during surgery and postoperatively. They can generally return to their presurgical treatment plan after the stress of surgery is past.

**Nursing Process for the Patient With Diabetes Mellitus**

**Data Collection**

A complete nursing history and physical examination should be carried out because diabetes affects every body system. Some areas on which to focus are shown in Table 40.8. It is especially important to assess each patient’s knowledge of diabetes and its care so that appropriate teaching can be done.

**Nursing Diagnoses, Planning, and Implementation**

Because diabetes affects so many different areas, nearly any nursing diagnosis may be appropriate. See the “Nursing Care Plan for the Patient With Diabetes Mellitus” for an example of the diagnosis Risk for Unstable Blood Glucose Level. The

</tbody>
</table>

The actual presence of the defining characteristics should be confirmed with the patient before choosing any nursing diagnosis.

Once diagnoses have been identified, planning should be done with both the patient and family. Diabetes affects not only the person with the disease, but the entire family. The desired outcomes for the plan of care are for the patient to be knowledgeable about and able to care for his or her disease and to prevent complications. Consult the dietitian, social worker, certified diabetes educator, home care nurse, outpatient education programs, and other resources as needed (“Home Health Hints”).

**Home Health Hints**

- Patients with newly diagnosed diabetes may be anxious and overwhelmed. Instruction may need to be repeated several times before they understand.
- Some home glucose monitoring devices have a memory that the nurse can access during the visit. It gives the date, time, and blood glucose result. This is a good indication of adherence with self-monitoring performed by patient or caregiver.
- Assist your patients in obtaining the necessary supplies to manage their diabetes. Many medical supply companies can deliver these supplies to the home. Work with your agency to identify reliable companies in your area.
- Remember to call the patient the day before performing a venipuncture for a fasting blood glucose and remind him or her not to eat after midnight.
- Older patients tend to skip meals. Assist them to identify easy but nutritious meals, such as frozen dinners that are low in sodium. Another option is Meals-on-Wheels, which is able to deliver meals that are tailored to special diets.
- If part of treatment is weight loss, encourage the patient to keep a food diary for three days to track areas in need of change.
- Prefilled syringes should be stored in the refrigerator flat or with needles pointing up. This prevents crystals from settling and clogging the needles. Allow syringes to come to room temperature before injecting.
- Patients can discard used syringes and needles in a hard plastic container such as a Clorox bottle with a screw top if red needle boxes are not available.
- If the patient has a visual or dexterity problem, suggest a syringe magnifier (check with the pharmacy) or a prefilled insulin pen.
- Help the patient learn to use a mirror to look at the bottom of the feet or have a family member examine the patient’s feet.
- Instruct the patient on the importance of wearing comfortable shoes. The patient should avoid sandals, high heels, flip flops, or ill-fitting shoes. If necessary, the HCP can request an orthopedic consult. A podiatrist can arrange for the patient to be measured and fitted with special shoes that properly fit his or her feet. Special shoes may be covered by Medicare.
- The patient should keep a pair of nonskid slippers at the bedside. If the patient needs to get up in the night to use the restroom, putting on secure slippers can help prevent the possibility of stepping on something and causing a foot injury.
- Due to decreased skin sensation in some persons with diabetes, hot water heaters should be set below 120°F (48.8°C).
- Even if patients have had diabetes for many years, observe them preparing and injecting their insulin. This provides an opportunity to praise good technique or correct bad habits.
- Diabetic patients with vision problems can become isolated and depressed. Assist your patient with obtaining vision aids that can help improve social outlets.
monitors but also provide training for the patient and family. You can obtain this information by calling local medical suppliers or by contacting the certified diabetes educator or discharge planner at your institution.

After discharge, the patient should be referred to outpatient diabetes classes for further instruction. If classes are unavailable or if the patient is unable to leave home, a referral to a visiting nurse should be made. It is usually advisable to have a nurse present for the patient’s first insulin injection at home. The ADA recommends that diabetes self-management education include information about the following:

- Disease process and treatment options
- Nutritional management
- Incorporating physical activity into lifestyle
- Using medications safely
- Monitoring blood glucose and using results
- Preventing, detecting, and treating acute complications
- Preventing, detecting, and treating chronic complications
- Personal strategies for psychosocial adjustment
- Personal strategies for health promotion and behavior change (ADA, 2014)

Two websites that might be helpful to both you and your patients are www.diabetes.org and www.lifeclinic.com/focus/diabetes/resources.asp.

Because many people with diabetes are older, it is important to be aware of their special needs (“Gerontological Issues”).

Syringe magnifiers and talking glucose meters are available for those with impaired vision.

Family members can be taught to draw up a week’s supply of insulin for the patient to store in the refrigerator. Family members should also be able to recognize signs and symptoms of hypoglycemia or hyperglycemia.

Home meal programs can help ensure an adequate diet.

Older adults should also have an emergency call system in the home and regular contact with family members or other support people.

**Gerontological Issues**

Diabetes care can be a challenge for many older adults.

- Syringe magnifiers and talking glucose meters are available for those with impaired vision.
- Family members can be taught to draw up a week’s supply of insulin for the patient to store in the refrigerator. Family members should also be able to recognize signs and symptoms of hypoglycemia or hyperglycemia.
- Home meal programs can help ensure an adequate diet.
- Older adults should also have an emergency call system in the home and regular contact with family members or other support people.

---

**NURSING CARE PLAN** for the Patient With Diabetes Mellitus

**Nursing Diagnosis:** Risk for Unstable Blood Glucose Level

**Expected Outcomes:** The patient will maintain at all times:

- HbA1c less than 7%
- Premeal glucose 70–130 mg/dL
- Postmeal glucose less than 180 mg/dL
Critically ill, hospitalized patient treated with insulin will maintain:
• All blood glucose measurements between 140 and 180 mg/dL.

Noncritically ill, hospitalized patient treated with insulin will maintain:
• Premeal glucose less than 140 mg/dL
• Random glucose less than 180 mg/dL.
(Verify individual goals with physician.)

**Evaluation of Outcomes:** Are blood glucose levels within predetermined parameters? Does patient show understanding of diabetes self-care?

**Intervention** Assess knowledge of diabetes self-care. **Rationale** Teaching should be initiated only if a knowledge deficit exists. **Evaluation** Does patient exhibit knowledge of diabetes self-care?

**Intervention** Assist patient to collaborate with HCP to determine appropriate blood glucose levels and action to be taken if glucose levels are too high or too low. **Rationale** Appropriate blood glucose levels may be different for each patient. The patient should know what blood glucose levels require notification of the HCP. **Evaluation** Does patient state appropriate blood glucose levels and action to take if glucose is high or low?

**Intervention** Teach patient to assess glucose levels before meals and at bedtime or as ordered by HCP. Ensure that patient knows how to obtain glucose monitor and instruction for home use. **Rationale** Good blood glucose control depends on knowledge of glucose levels and trends. **Evaluation** Does patient demonstrate correct use of glucose monitor or state how monitor and instruction will be obtained?

**Intervention** In a hospitalized patient who is taking nothing by mouth (NPO) or on continuous feeding, check glucose level every 4–6 hours around the clock. Check patient on insulin drip every 1–2 hours. **Rationale** Regular blood glucose monitoring is needed for scale insulin administration and maintaining glucose levels within safe parameters. **Evaluation** Is blood glucose monitoring carried out on an appropriate schedule?

**Intervention** Teach patient how to administer insulin or oral hypoglycemic agent after evaluating blood glucose. Ensure that meals are timed appropriately with medications. Replace any uneaten foods to prevent hypoglycemia. **Rationale** If most medications are taken without food to supply calories, hypoglycemia can occur. Check individual medication for specific instructions. **Evaluation** Does patient state appropriate meal and medication schedule?

**Intervention** Teach technique for administering insulin if indicated. **Rationale** The patient and family will be administering insulin independently at home. **Evaluation** Does patient demonstrate correct injection technique?

**Intervention** Observe for symptoms of hypoglycemia and hyperglycemia, and treat as needed. Teach causes, prevention, recognition, and treatment of hypoglycemia and hyperglycemia. **Rationale** If the patient has a good understanding of hypoglycemia and hyperglycemia, most episodes can be prevented. If hypoglycemia or hyperglycemia does occur, prompt treatment is essential to prevent complications. **Evaluation** Does patient state causes, prevention, symptoms, and treatment of hypo and hyperglycemia? Does patient carry fast sugar at all times?

**Intervention** Administer 15–20 g glucose or carbohydrate if blood glucose level falls below 70 mg/dL, or according to institution hypoglycemia guidelines. Contact RN or HCP if blood glucose is above 180 mg/dL. **Rationale** A “fast sugar” provides prompt treatment of hypoglycemia to prevent complications. Glucose levels over 180 mg/dL are associated with poor outcomes. **Evaluation** Does “fast sugar” resolve hypoglycemic episode within 15 minutes? If not, repeat. Are glucose levels within safe range?

**Intervention** Consult with dietician for nutrition therapy instruction. **Rationale** The dietician is trained to provide in-depth meal plan instruction. **Evaluation** Is patient able to state plan for obtaining appropriate meals?
REACTIVE HYPOGLYCEMIA

Reactive hypoglycemia, also called postprandial hypoglycemia, occurs when the blood glucose drops below a normal level following meals, usually below 50 mg/dL. Hypoglycemia is most often a complication of diabetes treatment, but at times it may occur without the presence of diabetes. It may be a warning sign of impending diabetes.

Pathophysiology and Etiology

Low blood glucose can occur as an overreaction of the pancreas to eating. The pancreas senses the blood glucose level rising and produces more insulin than is necessary for the use of that glucose. As a result, the blood glucose drops to below normal. It may be due to abnormally low levels of glucagon, or alternatively, to high levels of insulin. Other causes include previous GI surgery, enzyme deficiencies, and pregnancy, among others. Some experts believe that reactive hypoglycemia is a rare condition and that many “hypoglycemic” episodes are instead related to activation of the sympathetic nervous system for other reasons, without true hypoglycemia.

Signs and Symptoms

Low blood glucose causes release of epinephrine, which in turn causes the blood glucose to rise. Epinephrine release causes a fight-or-flight reaction, which may produce shaking, sweating, and palpitations. Headache, chills, and confusion may also occur. Symptoms are the same as those described earlier related to hypoglycemia in diabetes.

Diagnosis

Diagnosis may be based on a 5-hour glucose tolerance test, with below-normal readings between 2 and 5 hours. However, with the availability of home glucose monitors, it is now preferable for patients to monitor blood glucose levels at home. Readings should be taken in the morning on arising, 2 hours after each meal, at bedtime, and during symptoms of hypoglycemia. These results may then be taken to the physician for interpretation.

Therapeutic Measures

Treatment includes frequent small meals and a voidance of fasting. Simple sugars are avoided because they can aggravate symptoms. High-fiber foods, complex carbohydrates, and proteins are recommended. See Table 40.9 for a sample diet.

CRITICAL THINKING

**Mr. McMillan**
1. “Have you been eating or drinking more than usual? Have you been urinating more than usual? Do you get up at night to urinate? How is your appetite? Does anyone in your family have diabetes?”
2. Fatigue occurs because the glucose is unable to enter the cells without insulin, so they are starving.
3. Mr. McMillan is dehydrated because he is losing excessive amounts of urine as his kidneys lose excess glucose.

**Mrs. Evans**
1. Lantus insulin should be given the same time each day. Her order says each evening; any time in the evening is okay as long as it is consistent. Humalog is very fast acting so should be given no more than 15 minutes before eating—ideally when her food is ready to eat so no delay can occur.
2. She should be alert for low blood glucose 30 to 90 minutes after she receives her Humalog dose, the peak action time for Humalog. Eating her meal after her insulin dose should prevent hypoglycemia.
REVIEW QUESTIONS

1. The nurse knows a patient with type 1 diabetes needs more education when the patient makes which of the following statements?
   1. “I must take insulin pills for the rest of my life.”
   2. “I will count my carbohydrates at each meal and snack.”
   3. “I will monitor my feet carefully every day.”
   4. “I will try to keep my blood glucose between 70 and 130 mg/dL before meals.”

2. Diabetes is diagnosed when the fasting blood glucose is greater than ____ mg/dL.

3. An obese older adult patient is admitted to the hospital with pneumonia. The nurse notes that the patient gets up four times during the night to urinate. Which action by the nurse is most important at this time?
   1. Offer a bedside commode to the patient.
   2. Request an order for a fasting blood glucose test.
   3. Contact the dietitian for weight-loss counseling.
   4. Provide thorough perineal care after voiding.

4. A nursing home resident with a long history of diabetes requests a heating pad for cold, numb feet. What is the best response by the nurse?
   1. “Let’s soak your feet in hot water instead; that might be safer.”
   2. “Let’s elevate your feet to promote circulation and provide more warmth.”
   3. “I will bring you a heating pad; it will help your circulation in your feet.”
   4. “A heating pad can cause burns, but I can bring you some extra socks.”

5. Which statement by the patient with a new diagnosis of diabetes best shows understanding of instruction related to leading a healthy life and preventing complications?
   1. “I should see my doctor for a complete checkup every 6 months.”
   2. “I must check my feet daily.”
   3. “I should aim to keep my premeal blood glucose readings under 130 mg/dL.”
   4. “I will avoid all sweets and simple carbohydrates.”

SUGGESTED ANSWERS TO—cont’d

3. If Mrs. Evans receives insulin and misses her meal, she will likely develop hypoglycemia. If you know she is not feeling well, it would be best to hold her insulin for that meal until you speak with the HCP.

4. She can eat another fruit of similar nutrient amount from the exchange list. Applesauce, canned sugar-free peaches or pears, or other soft fruits would be appropriate.

Jeff
What kind of new job is it? What schedule is he working? Is it more physically strenuous than his previous job? Does it interfere with his usual meal schedule? What other changes has he experienced in his life that may have affected his blood glucose?

Mr. Jones
1. Poor circulation, neuropathy, and slow wound healing place Mr. Jones at risk for problems.

2. Circulation to the foot may be poor, and WBCs are sluggish if the blood glucose is high.

3. Any pressure on the foot while walking may further impair circulation. He should not bear weight on the affected foot.

4. If circulation to the area is poor, IV antibiotics may not reach the sore.

5. “Small red open area on right posterior heel, 1 cm × 1.5 cm, 2 mm deep, 2-cm area of yellow drainage on dressing.” In addition, many agencies are now taking instant photos of wounds to include in the chart. If no camera is available, a drawing of the size and shape is helpful.

6. Mr. Jones might benefit from involvement with a wound care nurse, dietitian, certified diabetes educator, and home care nurse. Assess for the need for a referral to a comprehensive diabetes education center.
Chapter 40  Nursing Care of Patients With Disorders of the Endocrine Pancreas 939

6. Which breakfast menu is most appropriate for a patient with diabetes?
1. Two eggs, two strips bacon, orange juice, coffee
2. Oatmeal with artificial sweetener, whole-grain toast, tea
3. One half grapefruit, cranberry juice, bagel with sugar-free jelly
4. One slice whole-grain toast with peanut butter, skim milk, orange juice

7. For which of the following blood glucose results would the nurse administer a “fast sugar”?
1. 48
2. 80
3. 126
4. 223

8. A patient who is preparing for surgery asks the nurse why the physician discontinued oral hypoglycemic agent orders and initiated sliding-scale insulin. Which response by the nurse is best?
1. “It helps us maintain better control of your blood glucose during surgery. You will most likely be back on your pills before you go home.”
2. “The stress of surgery often exacerbates diabetes. We will teach you how to give insulin before you go home.”
3. “Oral hypoglycemics are ineffective during times of stress. Insulin is the only way to keep your blood glucose under control.”
4. “The oral agents must not be controlling your blood glucose any longer. I will check and see which insulin you will be going home on.”

Understanding the Genitourinary and Reproductive System
LEARNING OUTCOMES

1. Explain the normal structures and functions of the reproductive system.
2. Identify the effects of aging on the reproductive system.
3. List data you should collect when caring for a patient with a disorder of the reproductive system.
4. Identify commonly performed tests used to diagnose disorders of the reproductive system.
5. Plan nursing care for patients undergoing each of the diagnostic tests.
The male and female reproductive systems produce gametes (sperm and egg cells [ova]) and facilitate the union of gametes in fertilization following sexual intercourse. The uterus provides for the developing embryo/fetus until birth.

**Female Reproductive System**

The female reproductive system consists of paired ovaries and fallopian tubes, a single uterus and vagina, and external genitalia (Fig. 41.1). The mammary glands may be considered accessory organs to the system.

**Ovaries**

The ovaries are a pair of oval structures, about 5 cm long and 2.5 cm wide, located on either side of the uterus in the pelvic cavity. The ovarian ligaments and the broad ligament help keep the ovaries and uterus in position.

The ovaries produce egg cells by oogenesis (meiosis), which begins in the fetus, continues through puberty, and ends at menopause. Typically, one mature ovum with its 23 chromosomes is produced and released approximately every 28 days, under hormonal control. Ovarian follicles produce estrogen and later, as the corpus luteum, secrete progesterone as well.

**Fallopian Tubes**

Each fallopian (uterine) tube is about 10 cm in length and extends from near the ovaries to the uterus. (Fig. 41.2) Its fimbriae draw an ovum into the tube, and ciliated epithelium transport either the ovum (or zygote if fertilized) toward the uterus.

**Uterus**

The uterus is a muscular organ about 8 cm long and 5 cm wide. Ligaments help keep the uterus in position, tilted anteriorly over the top of the bladder. During pregnancy, the uterus increases greatly in size and contains the placenta, which nourishes the fetus until birth. Rising oxytocin levels increases uterine contractions to bring about birth.

The uterus is divided into three layers: the external perimetrium, the myometrium, and the internal endometrium. The endometrium is a highly vascular mucous membrane, part of which is lost and regenerated with each menstrual cycle. During pregnancy, the endometrium helps form the maternal side of the placenta.

**Vagina**

The vagina extends from the uterine cervix to the vaginal orifice in the perineum. It lies between the urethra and the rectum.

After puberty, the vaginal mucosa is relatively resistant to infection. The normal bacterial flora of the vagina creates an acidic pH, which retards microbial growth. While present, the hymen provides mechanical protection.

**External Genitalia**

Also called the vulva, the female external genitalia include: the clitoris, mons pubis, and labia majora and minora (Fig. 41.3).

**Mammary Glands**

Enclosed within the breasts and surrounded by adipose tissue, the mammary glands produce milk after pregnancy (Fig. 41.4). During pregnancy, high levels of estrogen and progesterone prepare the glands for milk production. Prolactin causes the production of milk after pregnancy. Breastfeeding stimulates the release of oxytocin, which in turn stimulates the release of milk and contraction of the uterine muscle.

---

UNIT ELEVEN  Understanding the Genitourinary and Reproductive System

The Ovarian and Menstrual Cycles

The female reproductive cycles depend on follicle-stimulating hormone (FSH), luteinizing hormone (LH), estrogen, and progesterone (Table 41.1). These hormones bring about changes in the ovaries and uterus.

The menstrual cycle begins with the loss of the endometrium during menstruation, which lasts an average of 5 days. After the endometrium begins to proliferate again due to estrogen, FSH increases and so do ovarian follicles begin to develop, although typically only one will dominate. The secretion of LH also increases, peaking to cause ovulation.

After ovulation, the ruptured follicle becomes the corpus luteum, which begins to secrete progesterone in addition to estrogen. Progesterone stimulates further development of the endometrium. If the ovum is not fertilized, the secretion of progesterone decreases. Without progesterone, the endometrium cannot be maintained and begins to slough off in menstruation. FSH secretion begins to increase as estrogen and progesterone decrease, and the cycle begins again. An average cycle is 28 days.

Male Reproductive System

The male reproductive system consists of bilateral testes and a series of tubules, ducts, and glands. The glands contribute secretions to the sperm, producing semen.

Testes

The testes are located in the scrotum between the upper thighs, where the temperature is slightly lower than body temperature, which is necessary for the production of viable sperm. Each testis is about 5 cm long and 3 cm wide and contains the seminiferous tubules in which spermatogenesis (meiosis) takes place. In contrast to oogenesis, once started at puberty, spermatogenesis is a constant rather than a cyclical process and usually continues throughout life. FSH initiates
The **labia majora** are thick folds of skin and adipose tissue; hair grows on the lateral surfaces of the labia majora while the inner surfaces are hairless.

The **labia minora** are two thinner, hairless folds of skin just inside the labia majora.

The area inside the labia is called the **vestibule**; it contains the urethral and vaginal openings.

The **mons pubis** is a mound of hair-covered adipose tissue overlying the symphysis pubis.

A pair of mucus glands, called the **lesser vestibular glands** (or Skene's glands), open into the vestibule near the urinary meatus, providing lubrication.

Two pea-sized glands called the **greater vestibular glands** (or Bartholin's glands) sit on either side of the vaginal opening; their secretions help keep the vulva moist and provide lubrication during sexual intercourse.

The **clitoris** is a small mound of erectile tissue that resembles a penis. Its role is strictly sensory, providing a source of sexual stimulation.

Each breast contains 15 to 20 **lobules** separated by fibrous tissue and adipose tissue.

Each lobule consists of clusters of tiny, sac-like **acini** that secrete milk during lactation. Minute ducts drain the acini, merging to form larger ducts as they travel toward the nipple.

The ducts unite to form a single **lactiferous duct** for each lobe. Before reaching the nipple, the ducts enlarge slightly to form **lactiferous sinuses**.

Each duct ends in a tiny opening on the surface of the nipple.

A pigmented area called the **areola** encircles the nipple. Numerous sebaceous glands (that look like small bumps) dot the surface. Sebum from these glands lubricates the areola, helping prevent dryness and cracking during nursing.

Suspensory ligaments help support the breasts and also serve to attach the breasts to the underlying pectoralis muscles.
spermatogenesis. LH stimulates the secretion of testosterone, which contributes to the maturation of sperm. The secretion of inhibin is stimulated by testosterone; inhibin decreases the secretion of FSH, which helps keep the rate of spermatogenesis fairly constant. The functions of these hormones are summarized in Table 41.2.

**Epididymis, Ductus Deferens, and Ejaculatory Ducts**
A series of ducts lead sperm into and through the pelvic cavity where secretions are added; semen then exits the body via the urethra. The comma-shaped epididymis is a tube about 6 meters long that is coiled on the posterior side of a testis. Smooth muscle within its wall propels sperm from the testes into the ductus deferens. Also called the vas deferens, the ductus deferens extends from the epididymis in the scrotum to the ejaculatory duct within the pelvic cavity. Each of the two ejaculatory ducts receives sperm from the ductus deferens and the secretion of the seminal vesicle bilaterally. Both ejaculatory ducts propel semen through the urethra.

**Seminal Vesicles, Prostate Gland, and Bulbourethral Glands**
The male reproductive system includes bilateral seminal vesicles and bulbourethral glands, and a singular prostate (Fig. 41.5).

The mostly alkaline secretions of the male reproductive glands ensure that many sperm remain viable in the acidic environment of the vagina. The normal bacterial flora of the vagina create the acidic pH, but the pH of semen is about 7.4 and permits sperm to remain motile.

Urethra and Penis

The urethra is the last of the male reproductive ducts; its longest portion is within the penis. The penis is an external genital organ; its distal end is called the glans penis and when uncircumcised is covered with a fold of skin called the prepuce, or foreskin. Within the penis are three areas of erectile or cavernous tissue (Fig. 41.6).

When blood flow through these sinuses is minimal, the penis is flaccid (soft). Sexual stimulation causes the arterioles of the penis to dilate; the sinuses fill with blood, and the penis becomes erect and firm. This is brought about by parasympathetic impulses. The culmination of sexual stimulation is ejaculation (the expelling of semen from the urethra with force), which is brought about by peristalsis of the reproductive ducts and contraction of the prostate gland.

Spermatozoa

The head of the sperm cell contains 23 chromosomes. The midpiece connects the head to the flagellum. Sperm form in the seminiferous tubules of a testis and are stored in the epididymis.

Aging and the Reproductive Systems

For women, there is a definite end to reproductive capability; this is called menopause and is defined as having occurred when menses have ceased for 12 months. Menopause usually occurs between the ages of 45 and 55. Estrogen secretion decreases, and ovulation and menstrual cycles become irregular and finally cease. The decrease in estrogen has other effects as well. See Figure 41.7 for a concept map on the effects of aging.

For most men, testosterone secretion continues throughout life, as does sperm production, although both diminish with advancing age. Perhaps the most common reproductive problem for older men is enlargement of the prostate gland, called benign prostatic hyperplasia.

**FEMALE REPRODUCTIVE SYSTEM DATA COLLECTION**

Collecting data related to a woman’s reproductive health can seem challenging because of the complex relationship of physical and psychosocial factors. Hormones not only affect a multitude of body functions, they also can influence moods and mental functioning. Reproduction involves not only physical processes, but also relationships, role identification, and self-esteem issues.

**Normal Function Baselines**

Knowing about expected functioning of the reproductive system is your best preparation for data collection. Regular, relatively pain-free shedding of an appropriate amount of the endometrial lining of the uterus (menstruation) is expected from puberty through midlife or later. Intercourse is normally expected to be free of pain and infection, to occur when desired by both partners, to be satisfying, and generally to result in pregnancy within a few months unless precautions are taken. A pregnancy is expected to last approximately 40 weeks and to produce a healthy child. Physical and psychological sexual characteristics and function including libido (sexual desire) are expected to be adequately maintained by hormones. Sexual functioning, desire, and fertility are expected to change throughout the process of aging. Although individuals may vary somewhat from these expected descriptions, these serve as a baseline for collecting data related to possible disorders. Chapter 42 further defines specific female reproductive system disorders.

Much of what happens in female reproductive system disorders occurs inside the body and may not show external signs. Skill in asking appropriate questions, documenting patient statements, and describing observations is essential. Descriptions of symptoms should be thorough and follow the WHAT’S UP? format described in Chapter 1. Because many signs and symptoms of reproductive system disorders occur in a cyclic fashion, you or the health care provider (HCP) may ask the patient to keep an accurate written record of occurrences, noting times and dates to identify patterns.

**Health History**

Subjective data related to the female reproductive system include general personal information as well as menstrual, obstetrical, gynecological, sexual, family, and psychosocial histories. See Table 41.3 for specific data to collect.

**NURSING CARE TIP**

It is helpful to have women retain a monthly calendar of their menstrual cycles and bring it to any appointment during which discussion of the cycle may take place.

An obstetrical history includes number of pregnancies, pregnancy outcomes, and complications. These are generally documented using abbreviations of Latin words: G = number of pregnancies (from the Latin word gravida); P = births, whether alive or stillborn (regardless of number of fetuses) after 20 weeks’ gestation (from the Latin word para); A = abortions, whether spontaneous or therapeutic (from the Latin word abortus; a spontaneous abortion is sometimes

called a miscarriage). Roman numerals follow the letters to specify the number of each. For example, three pregnancies—twins, one single birth, and one spontaneous abortion—are recorded as GIII, PII, AI. This may also be written as G3P2A1. Some hospitals use additional notations such as number of premature or full-term births, number of living children, and number of therapeutic abortions. Be sure to follow your institution’s documentation policy.

**LEARNING TIP**
Remember the word gravida by thinking of gravity and that a woman typically is heavier when pregnant.

Also ask about any tests, surgeries, or treatments done on the reproductive organs and excretory system. Medications the patient is taking (for whatever reasons), height-to-weight ratio, and marked changes in weight may also provide significant data for diagnostic and care planning purposes related to reproductive system disorders.

**LEARNING TIP**
There are many things to remember when asking health history questions. Make up an index card for your pocket or purchase a prepared one for a handy reference.

Many nurses feel awkward asking reproductive history questions, and patients may also feel some uneasiness with this line of questioning. A matter-of-fact attitude, an assurance of confidentiality, and an adequate explanation about why the information is needed tend to encourage patient comfort and cooperation.

**Breast Examination**

**Palpation**

Palpation is the most important technique for breast examination because it can be used to identify alterations from normal consistency, to confirm the presence of lumps, and to locate areas of tenderness. Even mammograms are not sensitive enough to detect a small percentage of masses that can be felt by the patient or HCP.

**Breast Self-Examination**

Self-palpation during breast self-examination (BSE), if done regularly and thoroughly, may be even more sensitive than physician or nurse palpation because the patient becomes so familiar with her own breasts that she is more likely to notice subtle changes that an infrequently visited HCP might overlook. Because recent studies of BSE have failed to show a reduction in cancer deaths, some HCPs are now simply urging women to be familiar with their breasts and report changes, rather than teaching them to do monthly examinations. Other providers, however, continue to teach and recommend monthly BSE because they have seen it make a significant difference for many women. See Table 41.4 for additional objective data to collect.

**Patient Education**

If BSE is to be done monthly, a good time to perform it is 1 week after menses, when edema and swelling of normal breast tissue structures is at a minimum. For women who no longer have a regular menstrual period, any regular monthly schedule is fine. Although most women’s breasts are not exactly the same size, marked differences between the breasts or a change in the size of one breast should be checked with a HCP. Puckering or dimpling of skin, asymmetrical movement, and different pointing position of the nipples should also be reported. Whether the breasts are examined in parallel lines, a spiral formation, or a wedge pattern is not important. It is important, however, for the examination to be methodical and cover all areas of the breast, including the tail of Spence, which extends into the axilla (Fig. 41.8).

**NURSING CARE TIP**

Some women do BSE the day their telephone bill (or other bill) arrives each month because it is a dependable monthly reminder.

**CRITICAL THINKING**

Jilli

Jilli, age 24, states, “Why should I do breast exams at my age? I probably won’t get breast cancer until I’m older, if I get it at all.”

What should your response to Jilli include?

Why would this be a good time to provide education about health maintenance?

Suggested answers are at the end of the chapter.

**Diagnostic Tests of the Breasts**

**Ultrasound and Mammography**

Ultrasound can determine the density of the tissues and map the breast structures. This is mainly useful for distinguishing fluid-filled (cystic) lumps from solid tumors but can also be used to guide a needle for fine-needle aspiration of cystic fluid or core needle biopsies.

**Mammography** is a radiographic (x-ray) examination of the breasts. A special machine is used that spreads and flattens

*Note: A female physical examination is typically done by a physician or other trained provider.*

the breast tissue to a thin layer to more effectively show benign and malignant growths, which might be hidden by breast structures on typical chest examination (Fig. 41.9). Generally, at least two radiographs are taken of each breast, with the machine compressing the breast top to bottom and side to side to give comparison views from more than one angle. If suspicious or unclear spots are seen, additional views may be taken. New digital technology is now available that may be more effective in detecting cancers in younger women and women who have dense breasts. The actual procedure is the same...
for a digital mammogram, but the image is computerized, allowing the radiologist to look more closely at problem areas.

The American Cancer Society (2013) recommends the following for women:

- A screening mammogram at age 40 and yearly thereafter as long as they are in good health
- A clinical breast exam by a health professional every 3 years during the 20s and 30s, then yearly by a health professional at age 40 and thereafter
- Optional breast self-examination starting in the 20s; women should know how their breasts normally look and feel and report changes to their HCP
- Magnetic resonance imaging (MRI) and mammogram every year for women at high risk of breast cancer, such as women with BRCA1 or BRCA2 genetic mutations or strong family history

See Chapter 11 for more information.

**Patient Education.** Advise patients preparing for mammography to bathe and not to apply deodorant, powder, or any other substance to the upper body because these can cause false shadows on the test.

**Thermography, Tomography, and MRI**

Several other methods for diagnosis of breast disorders are available but are not commonly used. Thermography is a method of mapping the breast using photographic paper, which records temperature variations throughout the tissue in different colors. Computerized tomography (CT) or MRI can offer precise location of tumors without the displacement caused by flattening the breast for a mammogram.

**Biopsy**

If suspicious lesions are found, they may be further assessed with a biopsy. This may be done by surgically removing a portion of tissue or by aspirating fluid or cells through a needle that is placed into the lump or lesion.

Assessment of the patient’s psychological condition during breast diagnosis procedures is essential. Most women know someone who has had breast cancer. Although breast cancer screening procedures can seem routine to health care workers, they can be a cause of much anxiety for patients and their families. An understanding and calm nurse who can explain the procedures can help the assessment phase to be less traumatic.

**Laboratory Tests**

A blood test can be done to identify mutations in BRCA1 and BRCA2, genes that are associated with breast and ovarian cancer. By reviewing a woman’s family history, risk factors can be determined and testing can be offered. Women who test positive for either gene can discuss preventive treatments with their HCPs and also make their sisters and daughters aware of potential risk.

**Bone Health Assessment**

Bone health assessment is important for women of all ages. Teaching women early about the importance of good calcium and vitamin D intake will be of benefit later in life. Women of childbearing age produce estrogen, which helps prevent bone loss and works with calcium and other minerals to build bone. As women age and approach menopause, estrogen production slowly decreases, which decreases the processes of building and remodeling bone. Once a woman reaches menopause, her body is producing very little estrogen and therefore does not have the added benefit of bone protection. In fact, the body tends to break down more bone than it rebuilds. At this point in a woman’s life, dietary calcium and vitamin D requirements increase unless the woman is on hormone replacement therapy.

There is current debate about calcium and vitamin D supplementation for menopausal women. The U.S. Preventive Task Force (USPTF) issued a statement in 2013, based on research, against supplementation with vitamin D of 400 IU or less and calcium of 1000 mg or less because of the increased kidney stone risk and no evidence of preventing fractures. More research is needed in this area, but for now women should aim to get recommended calcium and vitamin D amounts through diet. If a woman is diagnosed with osteoporosis, she should speak to her HCP about a treatment plan. See Table 41.5 for recommendations for calcium and vitamin D intake from the National Institutes of Health Office of Dietary Supplements. See Chapter 6 for the calcium content of selected foods.

RDAs = recommended dietary allowances.

Diagnostic Tests of the Bones

In addition to recommending increasing the dietary intake of calcium and vitamin D, menopausal women older than age 50 who are not on hormone replacement therapy should be assessed for bone loss. The National Osteoporosis Foundation (www.nof.org) recommends bone density testing for all women over age 65 and for postmenopausal women under age 65 if they are at high risk (see Chapter 46).

The best test for bone density is a dual energy x-ray absorptiometry (DEXA) scan, which measures bone density at the hip or spine. This is a specialized x-ray that takes only 5 to 10 minutes to complete. A quantitative computed tomography (QCT) scan can also be done to determine bone density. Pharmacies or other outpatient facilities may offer tests of peripheral locations such as the heel. These are less sensitive but may still provide useful information that can be followed up with more extensive testing if indicated.

Hormone Tests

Hormone tests are commonly used to assess endocrine system function as it relates to reproduction. These tests may be used to measure potential fertility, to find reasons for abnormal menses, to assess hormone-producing tumors, and to determine whether treatments to adjust hormone levels have been effective. Some hormone tests are time-specific, so the samples can be rendered useless if not gathered within a certain time range.

**NURSING CARE.** Consult institution policy for specific instructions for each test. Explain the procedure to the patient and provide support. Women who are undergoing hormone tests may feel embarrassed, worried about their femininity and potential fertility, and depressed because of repeated tests. Some may fear loss of their spouse’s love (and perhaps the relationship) if they are diagnosed with alterations in hormone levels or function that lead to infertility.

Pelvic Examination

The pelvic examination allows visual inspection of the vagina and cervix, as well as sampling of mucus, discharge, cells, and exudates. Palpation of portions of the reproductive system and some treatments may also be done as part of the procedure (Fig. 41.10).

**NURSING CARE.** Be prepared to assist the HCP with the examination. Explain the procedure as you set out the supplies according to policy or provider preference. Have the patient empty her bladder, then remove her clothing and change into a gown (socks can remain on, and often give a
Bimanual Palpation

Because much of the reproductive system is not visible even with a speculum, bimanual palpation is often done during a pelvic examination. One hand is placed on the abdomen and the other gloved hand is inserted deeply into the vagina. The uterus and adnexa are moved about between the two hands to feel the size, shape, and consistency of the uterus and adnexa and to check for any abnormal growths.

NURSING CARE. Explain the procedure, and support the patient. Some women may be fearful, embarrassed, or tense and may find the procedure uncomfortable (see “Patient Perspective—Thoughts From a Sexual Assault Nurse Examiner”). Active relaxation strategies may decrease discomfort.

* WORD BUILDING *

bimanual: bi—two + manual—hands

adnexa: ad—together + nexa—to tie (usually refers to ovaries and tubes)

Patient Perspective

**Thoughts From a Sexual Assault Nurse Examiner**

When patients come in to see me, they are in crisis. They are unsure how or what to feel and whom to trust. They are very apprehensive. As patients give me the history of their assaults, they begin to trust me. They see someone who is interested in them and who believes them. By the time I actually start the head-to-toe physical examination, they know they are safe. Often, when I am performing the physical examination, I start small talk and take an interest in their lives that has nothing to do with the assault. When they are discharged from my care, they are more animated, talkative, and sometimes smiling.

The patient I remember the most was a child whose father was molesting her when her mother went to work. She was about 6 years old. When she came to the hospital, she wasn’t talking to anybody, let alone a nurse in a scary hospital at midnight. I spent 4 hours with this child. We colored, played, and talked about her brothers. By the end of the night, she allowed me to examine her. And she trusted me enough to let the physician come in and look at her. Unfortunately, in her young life, she had a reason to be scared. Her life became much worse before it got better. Her father tried to kill her mother and himself as a result of this.

So many of us have grown up with pop culture television, and we think of forensic examiners as professionals working with dead people. In fact, forensic nursing is caring for patients as it applies to the law. As a sexual assault nurse examiner, I care for people...
who have experienced interpersonal violence. I care for this special population of patients through the nursing process. I not only care for their physical trauma but also for their spiritual needs; lastly, I collect evidence for the prosecution of a crime. I advocate for their safety needs, and I help provide for their physical needs. I provide a bridge to the legal and mental health systems.

I began forensic nursing years ago when the concept was still new. We were navigating uncharted waters and were unsure what the end result would bring. What we quickly learned is, when you deliver good nursing care to patients, the end result can be a positive change in their lives, and that is the reward of the job: making a positive difference in patients’ lives, giving them some tools to help in their recovery process. Having the patient and family look at you and say “thank you for helping me” is what we all went into nursing for.

Becoming a sexual assault nurse examiner has made me become a more empathetic person, a more compassionate nurse, and a better citizen of my community.

Cytology

Cytology is the study of cells taken as tissue samples. Cells required for microscopic examination can be removed from the reproductive system in several ways. During a Papanicolaou (Pap) smear, one or more small samples of cells are gently scraped away from the surface of the cervical canal. They are then smeared or rolled onto microscope slides and sprayed with a fixative to preserve them for viewing, or placed into a fixative solution for later preparation and viewing in a laboratory. Cells may also be collected by conization, which involves removing a small cone-shaped sample from the cervical canal, or by punch biopsy, which removes a small core of cells. Endometrial biopsy specimens are samples of cells taken from the lining of the uterus by scraping with a small spoon-shaped tool called a curet, which is inserted through the cervix. Small biopsy specimens may also be taken by cutting or removing a suspicious lesion. Cells may be observed for changes indicative of hormonal secretion, cellular maturation, or abnormalities such as those seen with viral growths and cancerous or precancerous conditions. Results are reported simply as “normal, unclear, or abnormal.”

NURSING CARE. Consult the procedure manual or HCP concerning specific types of instruments to set up for biopsies and Pap smears. Cells die and degrade rapidly once removed from the patient, so they must be packaged securely for transport to laboratory facilities. Always label specimens carefully.

Prepare the patient by explaining the procedure and providing support. The woman may be fearful of cancer or other abnormality. Removal of the sample may cause pain, bleeding, swelling, or, later, inflammation, so the patient is monitored after the procedure and alerted to watch for and report these complications if they occur. After the procedure, document the woman’s status on the chart and record that the sample was sent to the laboratory. Advise the woman that if results are unclear or abnormal, additional testing will be done. Assure her that abnormal results have many causes and typically do not mean a cancer diagnosis.

CRITICAL THINKING

Reproductive Assessment

- How might the age of the patient change your approach, plans, and teaching for patients who have disorders of the reproductive system? Consider each of the following scenarios:
  1. A 2-year-old child is brought into the clinic by her mother because she has a foul-smelling discharge coming from her perineal area and a slight yellowish discharge from her vagina.
  2. A 21-year-old woman comes to the physician’s office where you work to obtain a renewal of her yearly birth control pill prescription. Your employer enforces regular checks for cervical changes by renewing the prescription only after a Pap smear is done. As you start setting out the Pap smear materials, your patient expresses some reluctance to have it done today because she is so sore already.
  3. Your 56-year-old patient comes in to “get things checked out” because she hurts every time that she and her husband have intercourse.

Suggested answers are at the end of the chapter.

Swabs and Smears

Swabs and smears are done to determine which microorganisms are causing infection, and consequently which antibiotics should be used.

NURSING CARE. If infection is suspected, add sample collection materials, including swabs, slides, and sterile saline in site-specific receptacles, and a gonorrhea/Chlamydia collection kit, to the pelvic examination equipment. Chlamydia samples are especially difficult to transport to laboratories, and special kits are available for this pathogen. Some microorganisms, such as yeasts and Trichomonas, can be identified well from smears on slides. Wet mounts are smears of discharge spread onto a slide. These must be taken to the microscope immediately after they are obtained. Sodium chloride and potassium hydroxide are dropped onto individual wet-mount slides before they dry to aid in identification of some microorganisms. Support the patient who may be anxious about possible sexually transmitted infections (STIs) and effects on relationships.

• WORD • BUILDING
  - conization: coniz—cone-forming + ation—process
Sonography

Ultrasound assessment (also called sonography) may be done to determine size, shape, development, and density of structures associated with the female reproductive system, as well as fetal measurements and some types of prenatal diagnoses. This procedure is especially useful for differentiating cysts from solid tumors and for locating ectopic pregnancies and intrauterine devices. Ultrasound may also be used to guide needles for obtaining samples of fluid or cells. Either external or vaginal transducers may be used to send and receive the signals for this procedure. Vaginal transducers are placed in a plastic sheath before insertion into the vagina. A full bladder may be required for some ultrasound tests.

NURSING CARE. Explain the procedure and support the patient. The pressure of the transducer on the skin or in the vagina may be painful if the adjacent structures are inflamed or swollen, or if the bladder is very full.

Radiographic Procedures

Several radiographic procedures may be used for diagnosis of reproductive system problems. Computed tomographic (CT) scanning and MRI are used to locate tumors of the reproductive system. Structures of the female reproductive system may also be outlined by taking x-ray pictures of cavities that have been filled with a radiopaque substance. During a hysterosalpingogram, dye is injected into the uterus until it comes out the ends of the fallopian tubes. This test is useful for identifying congenital abnormalities in the shape or structure of the uterus and blockages of the fallopian tubes.

NURSING CARE. Prepare the patient for a radiographic test according to agency policy, which may include a laxative, suppository, or enema. Ensure that the patient understands the procedure and that appropriate consents are signed as required. Ask about allergies to dye or iodine. Notify the supervisor immediately if the patient reports an allergy. After the procedure, assess for nausea, lightheadedness, and signs of allergic reaction and promote comfort, because some cramping can occur. Discharge teaching should include signs of infection and advice that the x-ray dye can stain clothing. Provide a perineal pad following the procedure and advise the patient to wear a perineal pad until vaginal drainage stops.

Endoscopic Examinations

Several types of endoscopic examinations are done to visually inspect internal areas to diagnose (and sometimes treat) reproductive system disorders. The names of the tests vary according to the area inspected, but all generally make use of a fiber-optic light and lens system, which is inserted through a tube called a cannula into a small incision. A laparoscopy is done to view the abdominal cavity and is useful for identifying problems such as endometriosis (Fig. 41.11). A salpingoscopy is performed to see the inside of the fallopian tubes and a hysteroscopy to see the inside of the uterus. A binocular microscope is used with an endoscope that is introduced into the vagina to closely study lesions of the cervix during a colposcopy. During culdoscopy, an endoscope is introduced into the vagina and through a small incision in the vagina into the cul-de-sac of Douglas, a cavity behind the uterus, to observe for abnormalities in this region (Fig. 41.12).

NURSING CARE. Preoperatively the patient is prepared for an endoscopic examination according to agency protocol. This generally involves asking the patient whether she has fasted as instructed, assessing vital signs, recording the time of last voiding, helping the patient into a gown, and ensuring that the consent form has been signed. General anesthesia may be given for some endoscopic procedures. Explain what to expect and provide support for the woman. She may be anxious about possible disorders. Postoperatively, provide comfort measures. These procedures produce almost no blood loss. The woman may experience pain in the neck, shoulders, and upper back if

**NURSING CARE TIP**

No one is really allergic to iodine—iodine is an essential element in our bodies. But some people may be allergic to dyes that contain iodine. It is still important to ask about iodine allergy, because that is how some women identify an allergy to dye.
Table 41.6 for a summary of diagnostic tests.

day and to report any fever or foul-smelling discharge. See the patient to report any bright bleeding after the operative procedure. Advise the patient to wear a pad until the drainage stops. Also instruct patient to observe the incision sites for redness, bleeding, or drainage, seeking evaluation by the physician promptly if these should occur or incision sites for redness, bleeding, or drainage, seeking evaluation by the physician promptly if these should occur or otherwise seeing the physician as directed for suture removal.

PATIENT EDUCATION. Advise the patient to observe the incision sites for redness, bleeding, or drainage, seeking evaluation by the physician promptly if these should occur or otherwise seeing the physician as directed for suture removal. If the endoscopic procedure was done transvaginally, provide a perineal pad following the procedure and advise the patient at ease while collecting data.

As with the female reproductive system, the male reproductive system is a complex interaction of both physical and psychosocial factors. Unlike women, however, men may find it much more difficult in our society to talk about or admit to having problems related to reproductive health. From toilet training through adulthood, men are expected to have behaviors associated with maleness. Unfortunately, by the time some boys reach manhood, their male identity is often defined by the successful functioning of their sex organs.

One of the important first steps in obtaining a male reproductive assessment is to provide a comfortable, nonjudgmental, confidential atmosphere for discussion. This means you must first be knowledgeable and comfortable with sexual issues. Although it may be challenging to ask questions about erection or ejaculation history, such questions may allow men to talk about difficulties they are experiencing. Be open and straightforward with all questions and answers. It may be necessary at times to use more commonly expressed sexual words instead of medical terminology. You will discover that many men do not know the function of their prostate gland or the difference between ejaculation and orgasm. Use the assessment as an opportunity to teach men the facts about their own sexual functioning.

Health History

Some basic questions to ask a male patient during a reproductive assessment are found in Table 41.7. As mentioned earlier, a professional, matter-of-fact attitude, along with an explanation as to why the questions are necessary, can put both you and the patient at ease while collecting data.

Physical Examination

The physical examination is generally performed by a physician or provider trained in physical assessments. The examination begins with the patient’s general appearance. He is observed for male patterns of hair growth on the head, face, chest, arms, and legs. Normal male pubic hair pattern is in a triangular shape, with hair growth up toward the umbilicus. The patient’s height and muscle mass are noted. Men are commonly taller than 5 feet, 6 inches tall, weigh more than 135 pounds, and have shoulders that are broader than their hips. The presence of excess breast tissue may indicate gynecomastia, from an excess of female hormones. Abnormal findings in either hair patterns or muscle mass often indicate a hormone imbalance.

The penis, scrotum, and testes (testicles) are examined by observation and palpation. On observation, the penis is normally flaccid (soft) and hanging straight down. The size can vary greatly and should not be a concern unless it is unusually small (microphallus) or edematous. The left testis typically hangs slightly lower in the scrotum than the right.

The penis is examined for warts, sores (evidence of STIs), swelling, curves, or lumps along the shaft. The examiner also makes sure the urethral opening is at the tip of the penis and not on the underside of the shaft (hypospadias) or on the dorsum of the shaft (epispadias). If the man is not circumcised (surgical removal of the foreskin), the foreskin should be pulled back carefully and the glans inspected for signs of inflammation or foul-smelling discharge. The provider should be sure to replace the foreskin in the forward position after the examination is completed.

The scrotum and testes are carefully examined and palpated. Both testes should be present and a normal size (approximately...

<tr>
<td>Mental Health</td>
<td>Are you experiencing stress? How do you deal with stress? Are you having problems with a sexual partner? Have you ever or are you experiencing performance anxiety or depression?</td>
<td>Decreased sexual desire and ability to have an erection may result from mental and/or emotional stress.</td>
</tr>
<tr>
<td>Circulatory/Respiratory</td>
<td>Have you ever been diagnosed with or treated for heart problems/surgery, high blood pressure, sickle cell disease, lung disease, or sleep apnea?</td>
<td>Decreased circulation can lead to inability to have usable erection; decreased respiratory function can result in activity intolerance, loss of erection.</td>
</tr>
<tr>
<td>Gastrointestinal</td>
<td>Have you ever been diagnosed or treated for liver infection/disease or bowel problems?</td>
<td>Liver infections/disease can lead to decreased testosterone and increased estrogen production, and loss of erection; gastrointestinal/bowel problems can lead to pain, loss of desire; surgery may result in loss of blood flow or innervation.</td>
</tr>
<tr>
<td>Musculoskeletal</td>
<td>Do you have painful joints, pelvic/lower back pain, or nerve damage?</td>
<td>Pain, loss of desire; limited movement/positions, loss of erection, ejaculation, and orgasm may result from musculoskeletal problems.</td>
</tr>
<tr>
<td>Neurologic</td>
<td>Have you ever experienced a stroke or suffered from multiple sclerosis, Parkinson’s disease, or other neurologic disorders?</td>
<td>Limited movement/positions, loss of sensations, and loss of control can result from neurologic problems.</td>
</tr>
<tr>
<td>Metabolic/Endocrine</td>
<td>Have you ever suffered from diabetes, obesity, or thyroid problems?</td>
<td>Diabetes mellitus can result in circulation problems, retrograde ejaculation, nerve damage; obesity can result in decreased male hormones, excess female hormones.</td>
</tr>
<tr>
<td>Genitourinary</td>
<td>Have you ever been diagnosed with a congenital deformity of the penis/testicles, suffered from prostate problems, or experienced erection/ejaculation problems? Have you ever been diagnosed with a sexually transmitted disease? When, what type, and how was it treated? That you are aware, was treatment successful? Do you have any lesions, pain, discharge, or swelling of the reproductive organs? Have you noticed any abnormalities/changes in size, shape, or color of your external reproductive organs? (Describe)</td>
<td>Difficulty with erection, penetration problems, retrograde ejaculation, or infertility may be associated with genitourinary abnormalities, stress, or medication use. Lesions, pain, discharge, swelling, or other abnormalities of the external reproductive organs may indicate infection, structural abnormalities such as varicocele, or other disease processes such as cancer.</td>
</tr>
</tbody>
</table>
The testes are egg shaped and should feel smooth and rubbery when lightly palpated between the thumb and fingers. The epididymis can be felt along the top edge and posterior section of each testis. The testes and scrotum are palpated for any lumps, cysts, or tumors. If a fluid-filled mass (hydrocele) is found, further evaluation should be done.

A simple noninvasive test called transillumination is used to determine if a mass is fluid filled or solid. With the room lights out, a flashlight is held behind the scrotum. If the mass is fluid, a red glow appears; if it is solid, it appears opaque.

Each spermatic cord (made up of veins, arteries, lymphatics, nerves, and the vas deferens) is palpated and should feel firm and threadlike. If a condition called a varicocele is present, the area feels like a bag of worms. A varicocele, which is swelling of the veins of the spermatic cord, is one of the most common problems associated with male infertility.

A digital rectal examination (DRE) may be done by an experienced practitioner. During DRE, the prostate gland is palpated by inserting a gloved, lubricated finger into the rectum while the man is in Sim’s position or standing and bending at a right angle over the exam table. The entire posterior lobe of the gland can be felt this way. The gland should feel slightly firm and without any lumps. If the prostate gland feels very hard or soft, enlarged, or contains any lumps, a rectal ultrasound with needle biopsy is often ordered. A swollen, painful prostate generally indicates that an infection is present.

Remind all men older than age 40 that unless they have had a complete removal of the prostate gland, they still need a DRE every year. Many men are under the impression that any prostate surgery means the gland has been completely removed. When simple surgery is performed, prostate tissue is left in the body and will begin to regrow over time. This prostatic tissue can become cancerous and needs to be monitored with a yearly DRE. See Table 41.8 for a summary of objective data to collect for the male reproductive system.

**Testicular Self-Examination**

All men after puberty should do a monthly testicular self-examination (TSE) to detect any tumors or other changes in the scrotum (Figure 41.13). See Box 41-1 for instructions that can be used to teach a man how to examine his testicles.

A varicocele, which is swelling of the veins of the spermatic cord, is one of the most common problems associated with male infertility.

---

**BE SAFE!**

Wrap the flashlight with clear plastic wrap to decrease the risk of contamination. Change the wrap between patients.

---

The male patient is also examined for inguinal hernias by pressing up through the scrotum into each of the inguinal rings while asking him to cough or bear down. Each side is examined separately while he is in the standing position. A hernia feels like a pulsation against the examiner’s fingertips.
Breast Self-Examination

Although breast cancer in men is rare, it can occur. Men, like women, should be familiar with their breasts and report changes.

Diagnostic Tests of the Male Reproductive System

Ultrasound

An ultrasound may be done to diagnose or evaluate a variety of male reproductive or genitourinary problems. A transrectal ultrasound may be done to diagnose prostate cancer. For this procedure, a rectal probe transducer is inserted into the rectum and sound waves are used to evaluate the prostate gland.

Note: A male physical examination is typically done by a physician or other trained provider.
Pelvic or scrotal ultrasound helps evaluate and locate masses. Ultrasound may also be done to guide a needle during a fine-needle biopsy.

NURSING CARE. Explain the procedure to the patient. An enema may be ordered before the procedure. No special aftercare is needed.

Cystourethroscopy

A cystourethroscopy may be done to evaluate the degree of obstruction by an enlarged prostate gland. For this procedure, a Foley catheter is inserted, and a dye is injected into the bladder. Radiographs are taken with the dye in the bladder and while voiding after the catheter has been removed.

NURSING CARE. Explain the procedure to the patient and assess for allergy to dye. Instruct the patient to void before the procedure. A sedative or analgesic may be ordered to help the patient relax during the procedure. If an analgesic is used, the patient will need to have someone available to drive him home.

After the procedure, intake and output are measured for 24 hours and alteration from the patient’s normal pattern, such as blood in the urine or absence of urination, is reported to the physician. Fluids are encouraged to promote excretion of the dye. A warm, moist cloth held over the urethra can assist with mild pain.

Laboratory Tests

PROSTATE-SPECIFIC ANTIGEN. Prostate-specific antigen (PSA) is a glycoprotein produced by prostate cells. The normal value of PSA is less than 4 ng/L. An elevated level indicates prostatic hypertrophy or cancer.

PROSTATIC ACID PHOSPHATASE. Prostatic acid phosphatase (PAP) is an enzyme that normally affects metabolism of prostate cancer cells. The normal value of PAP is less than 3 ng/mL. An elevated level indicates prostate cancer.

OTHER TESTS. If prostate cancer is suspected or diagnosed, additional tests may be done. Acid phosphatase may be elevated in metastatic prostate cancer. Alkaline phosphatase and serum calcium levels may be elevated if metastasis to the bone has occurred. See Table 41.9 for a summary of diagnostic procedures.

Tests for Infertility

Various hormone levels may be measured, including FSH, LH, testosterone, and adrenocorticotropic hormone (ACTH) to help determine causes of infertility in male patients.

Semen analysis may be done to provide information about causes of infertility or to evaluate whether a vasectomy has been effective. Semen may be analyzed for sperm count, motility, and shape. Other tests determine whether the semen contains adequate nutrients to support sperm, whether antibodies to the sperm are present, and the ability of the sperm to penetrate an ovum.

NURSING CARE. The patient is instructed to refrain from ejaculation for 3 days before collecting the semen sample to avoid altering findings. Generally, specimens are collected on three separate occasions over a period of 4 to 6 days. Masturbation and ejaculation directly into a sterile container are recommended to avoid loss of semen. Condoms and lubricants should be avoided. The sample should be taken to the laboratory within 1 hour of collection. Additional tests of the male reproductive system are discussed in Chapter 43.

### CRITICAL THINKING

**Jilli**

1. The answer should include basic breast health statistics and risks, as well as proper assessment practice and techniques as discussed in this chapter. She should be informed that although monthly BSE is not absolutely necessary, knowing her breasts and reporting changes is essential. Technique should be demonstrated and a return demonstration received during the visit.

2. Questions about breast health and self-assessment practices provide an opportunity for the nurse to educate a patient about health facts and technique. Patient questions can also be a cue to patient readiness and willingness to learn.

**Reproductive Assessment**

1. Calm fears. Explain simply. Allow the parent to stay with the child during the examination if appropriate. Consider whether it is possible that the child has been abused. If so, evidence needs to be collected and a report

Continued
filed with the appropriate child protection authorities. Check with your supervisor if you believe this is a possibility. Teach the child that this is a normal part of the body that is to be protected and taken care of.

2. Assess knowledge and maturity. Prepare the patient for a Pap smear and for swabs and smears. Teach while getting supplies ready. Explain that vaginal soreness usually needs to be treated and that the physician must know more about the problem to do so effectively. Explain that inflammations can interfere with Pap smear results, so testing may have to be repeated after treatment. Explain culture and sensitivity testing. Teach about risk reduction and inform that oral contraceptives do not offer a barrier against sexually transmitted infections.

3. Try to put the woman at ease through general conversation. Set out supplies for a Pap smear (if needed) and for swabs and smears. Teach while getting supplies ready. Discuss aging and the effects of decreased estrogen in general and specifically on vaginal tissues. Inform her that there are several ways to deal with problems resulting from decreased estrogen, such as oral hormonal replacements, water-soluble vaginal lubricants, vaginal creams, estrogen patches, and estrogen receptor modulator medication.

**Tony**

1. Palpable scrotal changes can result from a variety of reproductive and/or genitourinary abnormalities. Before Tony’s question can be answered, a complete history needs to be obtained and a clinical exam of the genitalia performed.

2. The history should explore:
   - If TSEs are regularly performed and if changes have been noted.
   - If Tony is sexually active and has, recently or in the past, been knowingly exposed to an STI.
   - If there has been pain associated with the “bump” or exudate noted from the penis.
   - The assessment, done by a physician or primary care provider should include:
     - Visual inspection of the size, shape, symmetry, and color of the scrotum and its contents.
     - Palpation to assess for abnormalities and pain.
     - Cultures to rule out STIs.
     - An inguinal exam to rule out herniation. Ultimately, based on the patient’s report, a testicular tumor should be ruled out.

---

**REVIEW QUESTIONS**

1. When obtaining the history of a 17-year-old male during a sports physical, what important screening practice should be discussed?
   1. Yearly DRE
   2. Monthly TSE
   3. Yearly PSA
   4. Bimonthly bimanual examination

2. A patient has just had a laparoscopy to investigate the causes of her infertility. Why should the nurse instruct her to lie flat in the bed for a few hours?
   1. She could rupture her abdominal incision.
   2. Her blood pressure will be low because of blood loss.
   3. The carbon dioxide left over from the test will travel upward and cause pain.
   4. Her uterus needs to be at the same level as her heart to prevent excessive swelling.

3. A 66-year-old woman is seen in an outpatient clinic for routine care. What teaching should the nurse provide related to bone health?
   1. “You should be taking in at least 1200 mg of calcium and 600 international units of vitamin D in your diet.”
   2. “The benefit of eating red meat outweighs the risk as you age. You should eat 6 ounces three times a week.”
   3. “Your bones are protected by the calcium you ate in your younger years; increasing intake now will not help your bones.”
   4. “It is important to take a calcium and vitamin D supplement, because it is difficult to get enough in your diet.”
Chapter 41  Genitourinary and Reproductive System Function and Assessment

4. How would the nurse document the reproductive history of a pregnant woman who is in her fourth pregnancy, has two living children ages 3 and 5, and had one miscarriage?
   1. P4G2M1
   2. G4P3P5M1
   3. P4G35A1
   4. G4P2A1

5. What is the role of the LPN/LVN in physical assessment of the male and female genitals?
   1. Perform a complete history and physical assessment of the genital area.
   2. Collect specimens under the supervision of the RN.
   3. Prepare the patient for what to expect during the practitioner’s examination.
   4. The LPN/LVN does not have a role in assessment of the reproductive system.

Answers can be found in Appendix C.

LEARNING OUTCOMES

1. Explain the pathophysiology of each of the disorders of the female reproductive system.
2. Describe the etiologies, signs, and symptoms of each disorder.
3. Identify tests used to diagnose female disorders.
4. Describe current therapeutic management for each disorder.
5. List data to collect when caring for patients with disorders of the female reproductive system.
6. Plan nursing care for female patients with reproductive disorders.
7. Explain how you will know if nursing interventions have been effective.
8. Compare different forms of contraceptives and their effectiveness.
Reproductive system disorders can be frightening, irritating, frustrating, embarrassing, and in some cases fatal. They involve not just body parts but also roles, relationships, and sense of identity and purpose in life. Nurses can play an important role in helping women with these disorders. Women’s health is an area in which much research is being done. The Nurses’ Health Study, conducted at Harvard Medical School, is a large ongoing study on many topics related to women’s health. You can learn about it at www.nurseshealthstudy.org.

BREAST DISORDERS

Benign Breast Disorders

Much has been done in recent years to educate the general public concerning breast cancer. It is the most commonly diagnosed cancer in women (Centers for Disease Control and Prevention [CDC], 2011). Heightened awareness of the risks of breast cancer, however, sometimes results in excessive anxiety among women with benign breast conditions. The following section covers benign, or noncancerous, breast disorders.

Cyclic Breast Discomfort

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** The most common breast symptoms result from cyclic variations in hormone levels. Swelling, tenderness, and sometimes pain (mastalgia) can be related to hormone-mediated changes within the breast tissues that prepare them for their potential role of breastfeeding.

**TREATMENT.** If persistent or severe, these symptoms can be treated with oral contraceptives that modify hormone levels or nonsteroidal anti-inflammatory drugs (NSAIDs) to control pain. Explaining that cyclic discomfort is temporary and not from a disease process helps to reduce fears.

Fibrocystic Breast Disease

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Overresponsiveness of cells in the breasts to hormonal stimulation (especially estrogen) can cause long-term changes resulting in replacement of normal tissue with fibrous tissue, overdevelopment of cells, and blockage of ducts so that cysts form around trapped fluid. This makes the breasts feel somewhat hard and lumpy, and sometimes painful. These changes often occur during the reproductive years, and can respond to hormonal variations during the menstrual cycle. Fibrocystic changes usually subside with menopause.

**DIAGNOSIS AND TREATMENT.** Fibrocystic breast changes can be identified on palpation. A mammogram or ultrasound may be done to assist in diagnosis. A biopsy may be done to rule out cancer. Treatment for fibrocystic breast changes is based on patient symptoms. Often, no treatment is necessary. Analgesics, primarily NSAIDs, help reduce discomfort. Herbal remedies such as evening primrose oil, or supplemental vitamin therapy may offer symptomatic relief, but these therapies remain controversial. Limitation of dietary fat and caffeine and addition of oral contraceptive use may help control hormonal changes.

Although fibrocystic changes are not cancerous, more frequent mammography or ultrasound may be advised because fibrocystic changes can make it more difficult to feel early cancerous lumps during breast examination. Some types of breast cysts are associated with a higher cancer risk. Needle aspiration may be used to treat cystic lesions.

Mastitis

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Breast infection with inflammation (mastitis) occurs as a result of injury and introduction of bacteria into the breast. This condition most commonly occurs while breastfeeding. The breast becomes swollen, hot, red, and painful and can form an abscess.

**TREATMENT.** Mastitis can be treated either with antibiotics or by incision and drainage (I&D) of the abscessed area. NSAIDs, warm packs, and breast supports are often used to control pain and swelling.

**NURSING CARE AND PATIENT EDUCATION.** Teach the patient to wash her hands carefully to prevent the spread of infection. If the patient is breastfeeding, it is often continued to promote drainage of the breast, mother–infant bonding, and infant nutrition. The infant is often already colonized with the bacteria so further exposure is not thought to be detrimental.

• Word Building •

- mastalgia: mast—breast + algia—pain
- fibrocystic: fibro—fibrous + cystic—saclike
- mastitis: mast—breast + itis—inflammation
**NURSING CARE TIP**

To help prevent mastitis in a breastfeeding mother, recommend frequent changes in feeding positions to empty all portions of the breast, as well as good hand hygiene techniques when handling the breasts. Also recommend breastfeeding frequently, not restricting the length of feed.

---

**Malignant Breast Disorders**

**Pathophysiology and Etiology**

Breast cancer is an abnormal growth of breast cells. It can arise from the milk-producing glands, the ductal system, or the fatty and connective tissues of the breast.

Research has identified factors that increase the risk of breast cancer: increasing age; personal or family history of breast, ovarian, or prostate cancer; a high-fat diet; high alcohol intake; treatment with estrogens (especially when used without progestins); early menarche; late menopause; and first pregnancy after age 25.

**Signs and Symptoms**

A lump or thickening of breast tissue, or a change in the shape or contour of a breast can indicate breast cancer. A tumor can also cause dimpling of the overlying skin or retraction of the nipple. Clear or bloody nipple discharge can occur. Swelling, tenderness, or discoloration of the breast can indicate inflammatory breast cancer, a rare but deadly form. Breast symptoms have many causes, but all should be investigated by a health care provider (HCP).

**Prevention**

Breast cancer risk can be reduced by exercising moderation in fat and alcohol consumption and using nonhormonal methods for birth control and menopausal symptoms. Breastfeeding may also reduce risk, even in women who have late first pregnancies (see “Evidence-Based Practice” box). However, many factors cannot be controlled, so the importance of early detection cannot be overemphasized. Recent research has discovered genes (BRCA1 and BRCA2) that are linked with susceptibility to breast cancer. These findings offer the possibility of very early identification of women at the most risk of developing breast cancer (and also ovarian cancer for those with BRCA1). These women can then be monitored closely for breast changes and receive early treatment if cancer develops. Some women choose to have bilateral prophylactic (or risk-reducing) mastectomy.

Before any genetic testing, patients should be counseled by a professional who is qualified to explain and interpret the results. It is also important to review risk and benefits of doing testing before having testing done. Some insurance plans don’t cover the expensive cost of such testing. More information regarding BRCA testing can be found at www.cancer.gov/cancertopics/factsheet/Risk/BRCA.

---

**EVIDENCE-BASED PRACTICE**

**Clinical Question**

Does breastfeeding reduce risk of breast cancer?

**Evidence**

A systematic review of 31 research studies was undertaken (Yang & Jacobsen, 2008). Eleven found that breastfeeding significantly reduces breast cancer risk, and 13 studies found a reduced risk only with extended lactation. Kotopoulous et al (2012) found that breastfeeding protects against BRCA1 but not BRCA2-associated breast cancer.

**Implications for Nursing Practice**

There are many reasons to advise women to breastfeed their babies in addition to obvious benefits for the babies. Possible protection against breast cancer is one reason. Women with the BRCA mutation should be advised of the benefits of breastfeeding.

**REFERENCES**

**Diagnosis Tests**

Breast self-examination (BSE) and clinical breast examinations play an important role in cancer identification. Cancerous growths tend to be harder, less mobile, less painful, more irregularly shaped, and have less clearly defined borders than benign growths. The prognosis is good for women who have breast cancers removed in the early stages but gets worse when treatment begins during later stages of the disease process. Teaching and encouraging regular use of BSE and appropriate use of mammography can save lives. See Chapter 41 for more about BSE and for explanations about diagnostic tests used to assist in determining whether tumors of the breast are malignant.

**Staging**

The spread (metastasis) of cancerous cells from the primary site to other areas of the body by way of the blood or lymph is denoted by staging classifications 0 to IV (see Chapter 11). Lower numbers indicate less cancer spread.

**Therapeutic Measures**

The five main treatment options for breast cancer are surgery, radiation therapy, chemotherapy, hormone therapy, and targeted...
therapy. These options may be used separately or in combination depending on the condition of the patient and the stage of the disease. Patients may also choose complementary and holistic therapies. Immunotherapy is a new and promising field of breast cancer treatment that uses the body’s immune system to fight cancer. A number of immunotherapies are currently being studied, including the use of vaccines.

SURGERY. A **lumpectomy** removes just the tumor and a margin around it. A **mastectomy** may be partial (removing only part of the breast), simple (removing the breast tissue of one or both breasts), or radical (removing breast tissue, underlying muscle, and surrounding lymph nodes). The amount of tissue removed varies depending on the size, nature, and invasiveness of the cancer. Surgical practice has shifted from radical mastectomies to more breast-conserving surgeries with the addition of radiation therapy, resulting in survival rates similar to those for radical mastectomy. Surgeries to remove cancerous breast tissue can be disfiguring and have profound effects on a patient’s body image and self-esteem.

RADIATION THERAPY. Radiation can be administered externally or internally to attack the rapidly dividing cells of a tumor. Although radiation affects all rapidly dividing cells in its path, including healthy cells, radiation to an area of the breast just surrounding the tumor bed reduces the incidence of side effects. It is usually used after surgery to reduce the risk of cancer recurrence or spread.

CHEMOTHERAPY. Chemotherapy kills all rapidly dividing cells, not just breast cancer cells, which leads to many side effects. This therapy may be used alone or in combination with other therapies. Newer chemotherapy options use higher doses over a shorter treatment period to reduce side effects (see Chapter 11).

HORMONE THERAPY. Hormone therapy may be used to deprive cancer cells of hormones that stimulate their growth. Because breast cancer cells are often estrogen sensitive, this may be accomplished by decreasing circulating estrogen levels with drugs or by blocking the use of estrogen by cancer cells. Interference with estrogen levels, however, may produce menopausal symptoms and increase the risk of osteoporosis and heart disease. Table 42.1 lists estrogen antagonists.

**Continued**
TARGETED THERAPIES. Targeted therapies attack specific molecular agents or pathways involved in the development of cancer. Some targeted therapies are given to intensify positive body responses (e.g., stimulate the immune system) or to decrease negative body responses. Examples include biological response modifiers such as interferons, tumor necrosis factor, interleukins, and various experimental immunotherapy formulations. Two drugs that target the protein HER2, which is found in larger than normal amounts on the surface of breast cancer cells, are trastuzumab (Herceptin) and lapatinib (Tykerb). Another drug, bevacizumab (Avastin), works by blocking the growth of new blood vessels that cancer cells depend on to grow and function. Targeted therapy is an area of much research and is likely to expand greatly during the next few years. Alternative therapies are also available for many cancers. See Chapter 5 for information about helping patients evaluate alternative and complementary therapies. The American Cancer Society and cancer treatment centers also have people who can answer questions about experimental and alternative therapies and discuss research findings. For more information about breast cancer, visit the American Cancer Society at www.cancer.org. Other helpful sites are www.breastcancer.org and ww5.komen.org.

**Nursing Care**

See the “Nursing Care Plan for the Patient Undergoing a Mastectomy.” In addition to the diagnoses covered, the patient will need diagnoses for postoperative pain. See Chapters 10 and 12, respectively, for additional interventions for pain and postoperative patients.

**Critical Thinking**

**Julie**
- Julie, age 32, reports pain and grapelike “lumps” in her breasts, and her nurse practitioner diagnoses fibrocystic changes.

1. What questions would you ask to further assess Julie’s symptoms?
2. What can you teach Julie to help her control her symptoms?
3. What can Julie do to remain vigilant for more concerning changes in her breasts?

*Suggested answers are at the end of the chapter.*
### NURSING CARE PLAN for the Patient Undergoing a Mastectomy

**Nursing Diagnosis:** *Anxiety* related to uncertainty about diagnosis, prognosis, and treatments

**Expected Outcomes:** The patient will verbalize and demonstrate a decrease in anxiety.

**Evaluation of Outcomes:** Does the patient report a decrease in anxiety following education and explanation of the procedure? Do patient’s vital signs, verbal, and nonverbal behavior suggest a decrease in anxiety?

**Intervention** Assess vital signs and observe verbal and nonverbal behavior. **Rationale** An increase in blood pressure, pulse, and respirations as well as observation of mild to severe agitation may indicate anxiety.

**Evaluation** Are the patient’s vital signs within normal range for the patient? Is verbal and nonverbal behavior consistent with anxiety?

**Intervention** Assess patient’s current knowledge of the procedure and level of anxiety related to the procedure. **Rationale** Assessment of current knowledge provides a baseline for teaching. **Evaluation** What does the patient know?

**Intervention** Teach patient what to expect about the surgical experience based on patient’s understanding, concerns, and willingness to learn. **Rationale** Knowledge dispels unreasonable fears and helps patient to prepare to cope with stressors. **Evaluation** Does patient evidence adequate understanding of the procedure and what to expect afterward?

**Intervention** Support and clarify the HCP’s explanations, answer questions, and refer to knowledgeable sources. **Rationale** The patient may not remember or understand what the HCP said. **Evaluation** Does patient have accurate information? Are appropriate referrals made?

**Nursing Diagnosis:** *Risk for Ineffective Breathing Pattern* related to pain with chest movement

**Expected Outcome:** The patient will have an effective breathing pattern with clear lung sounds and \( \text{SpO}_2 \) of 95% or above.

**Evaluation of Outcome:** Are respirations regular, easy, and unlabored? Are respiratory rate and oxygen saturation within a normal range for the patient? Are lung sounds clear?

**Intervention** Assess patient’s vital signs, oxygen saturation, pain level, and lung sounds. **Rationale** Pain contributes to shallow breathing, which can affect vital signs, \( \text{SpO}_2 \), and lung sounds. **Evaluation** Are the patient’s vital signs and oxygen saturation within normal range for the patient? Does patient report pain at an acceptable level? Are lung sounds clear?

**Intervention** Medicate to relieve pain as necessary. **Rationale** Pain may inhibit deep breathing efforts. **Evaluation** Does patient evidence pain or guarding during chest movement? Does analgesic help?

**Intervention** Encourage deep breathing and coughing each hour. **Rationale** This helps to loosen secretions and to prevent atelectasis, pneumonia, and inadequate oxygenation of tissues. **Evaluation** Does chest sound clear? Are skin color and oxygen saturation adequate?

**Intervention** Encourage use of an incentive spirometer each hour when awake. **Rationale** To encourage deep breathing. **Evaluation** Does patient use spirometer correctly?

**Nursing Diagnosis:** *Risk for Ineffective Tissue Perfusion* related to damage to blood and lymph vessels and tension at surgical incision site

*Continued*
### NURSING CARE PLAN for the Patient Undergoing a Mastectomy—cont’d

**Expected Outcome:** The patient’s incision will heal by primary intention without excessive bleeding or swelling.

**Evaluation of Outcome:** Are edges of the incision well approximated, with scant bleeding/serous drainage, and mild edema/erythema?

**Intervention** Monitor vital signs and oxygen saturation according to agency policy and as necessary. **Rationale** Vital signs and oxygen saturation affect tissue perfusion and oxygenation. **Evaluation** Are vital signs and 

**Intervention** Avoid use of the affected arm for blood pressures, venipunctures, and injections. **Rationale** Restrictive and invasive procedures might further compromise tissue integrity of the affected arm. **Evaluation** Is the arm protected?

**Intervention** Assess incision for bleeding, amount and color of drainage, and swelling. Empty drain device prn. **Rationale** Excessive bleeding or swelling can compromise tissue perfusion. **Evaluation** Does incisional area look swollen, smooth, or shiny? Are drainage amount and color appropriate?

**Intervention** Measure circumference of arms daily and compare. Report changes. **Rationale** Swelling causes an increase in circumference and impairs circulation. **Evaluation** Is affected arm larger than unaffected arm?

**Intervention** Elevate affected arm if swelling occurs. **Rationale** Gravity aids fluid return to the heart. **Evaluation** Does elevation reduce swelling?

**Intervention** Place items where patient can easily reach them. **Rationale** Excessive movement of the affected arm may exert tension on incision and increase bleeding. **Evaluation** Can patient reach items without abducting the arm more than 90 degrees?

**Intervention** Encourage postmastectomy exercises of the affected arm according to agency policy. **Rationale** Appropriate exercise promotes circulation, preserves muscle and joint function, and increases self-care ability. **Evaluation** Is patient moving the arm appropriately and gradually increasing range of motion and self-care ability?

**Intervention** Teach postoperative self-care and signs and symptoms of ineffective healing to report. **Rationale** Early assessment and intervention help prevent the development of serious complications. **Evaluation** Does patient demonstrate and verbalize understanding of appropriate postoperative self-care?

**Nursing Diagnosis:** Risk for Ineffective Coping related to cancer threat and body image disturbance

**Expected Outcomes:** The patient will verbalize ability to cope and will seek help and support appropriately.

**Evaluation of Outcomes:** Does patient take an interest in care of condition? Does patient ask appropriate questions related to care and verbalize appropriate concerns?

**Intervention** Observe patient’s interest in self-care, ability to problem solve, and level of family or other support. **Rationale** Poor self-care, problem-solving skills, and lack of support may indicate a risk for ineffective coping. **Evaluation** Does patient solve problems appropriately? Are family members or other support persons present? Is patient taking an active interest in her personal appearance?

**Intervention** Use therapeutic communication and listening skills to allow patient to share concerns. **Rationale** Loss of a breast disturbs many aspects of body image, and cancer threatens one’s sense of security and stability in life. **Evaluation** Is patient able to share concerns?

**Intervention** Help patient remember previous successes in coping and strategies used. **Rationale** Memory of prior success can encourage hope for future success. **Evaluation** Does patient possess appropriate coping strategies?
NURSING CARE PLAN for the Patient Undergoing a Mastectomy—cont’d

**Intervention** Provide accurate information according to agency policy. **Rationale** Fear of the unknown can increase anxiety and reduce coping. **Evaluation** Does patient relate understanding of follow-up treatment?

**Intervention** Refer to appropriate agencies for further support as needed (e.g., American Cancer Society, Reach for Recovery, local support groups). **Rationale** Social support can assist individuals to meet their needs while developing effective coping skills and strategies. **Evaluation** Does patient have resources to call on as needed?

See Table 42.2 for a breast cancer summary.

**Breast Modification Surgeries**

**Mammoplasty** is surgical modification of the breast. This may be done to restore a normal shape after removal of cancerous tissues. Many women, however, undergo mammoplasty electively to reduce or increase the size or to improve the shape of their breasts. Because nurses are very aware of the dangers involved with surgery, psychosocial issues may seem to be a trivial reason to voluntarily assume such risks to life and health. However, body image is an important component of quality of life. Patients’ informed decisions should be respected if they choose this surgery. It is essential that you present a caring and nonjudgmental attitude.

BSE = breast self-examination; CBE = clinical breast examination.

**Breast Reduction and Mamtopexy**

Generally, in breast reduction operations the nipple is separated from the surrounding tissue except for a small section with the blood vessels and nerves that supply it (Fig. 42.1). A large wedge of tissue is removed from the bottom of the breast, the edges are sewn together, and the nipple is reimplanted in a

---

**WORD BUILDING**

**mammoplasty:** mamm(o)—breast + plasty—to mold

---

higher position. This not only decreases the overall size of the breast, which may help with back, neck, and head pain, but it also corrects excessive sagging—a common problem for women with large breasts.

A mastopexy involves the removal of some skin and fat with subsequent resuturing so that the breast tissues are held higher on the chest to correct sagging breasts. This procedure usually does not remove as much tissue as a breast reduction.

**Augmentation and Reconstruction Mammaplasty**

**Augmentation** is a surgery to increase the size of the breasts. An implant—either a bag containing saline solution or silicone gel or a transplanted portion of the patient’s own body tissues from another area—is inserted through an incision and positioned either under or over the pectoral muscles (Fig. 42.2).

For reconstructive mammaplasty, use of the patient’s own tissues is generally safer than use of artificial implants because no foreign material is introduced into the body. For situations in which significant amounts of tissue are needed for reconstruction, a portion of tissue may be moved from one area of the body to another as a pedicle graft. Pedicle literally means “little foot” because the graft remains attached to a stalk (containing the blood vessels and nerves) somewhat resembling a little leg with a foot (the graft) attached.

Figure 42.3 shows two options for mastectomy graft repair. Tissue from the buttock area or the abdomen may also be grafted onto a mastectomy site without a pedicle.

**Complications**

Any surgery can be complicated by infection or impaired healing. The use of silicone implants has been less than satisfactory for many women. Some women have experienced hardening of breast tissues, and others have developed serious autoimmune problems after receiving silicone gel implants. Although actual etiologies of all the problems are uncertain, many surgeries have been undertaken recently to remove silicone implants, and saline implants are now more common.

**Nursing Care and Patient Education**

Carefully assess the healing process when changing dressings and explain to the patient how to assess healing, because not all tissues successfully attach at the new site. Failure of attachment can require surgical revision. Signs of poor attachment include unnatural color of the incision, graft, or surrounding tissues; swelling; drainage; gaping incision lines; and sloughing of the graft or edges of the site.

MENSTRUAL DISORDERS

Flow and Cycle Disorders
Pathophysiology, Etiologies, and Signs and Symptoms

There are many types of menstrual abnormalities (Table 42.3). Causes can include stress, pregnancy, hormonal imbalances, metabolic imbalances (such as obesity, anorexia nervosa, and loss of too much body fat through excessive exercise), tumors (both benign and malignant), infections, organ diseases (such as liver, kidney, or thyroid disease), blood or bone marrow abnormalities, and the presence of foreign bodies in the uterus (such as intrauterine devices, IUDs). Menstrual abnormalities can be distressing and can result in anemia, persistent fatigue, and sexual dysfunction. Establishment of a comfortable and open professional relationship between a woman and her HCP is essential for communication about such concerns.

Diagnostic Tests

Appropriate testing to determine the cause of menstrual abnormalities involves a thorough history and physical examination. Papanicolaou (Pap) smear, cervical and vaginal cultures, laparoscopy, ultrasound, endometrial biopsy, pregnancy testing, urine testing, and blood testing may be done to screen for any of the disorders that can influence the menstrual cycle and flow.

Therapeutic Measures

Medical treatment of menstrual disorders often involves manipulation of hormone levels or use of NSAIDs. Surgical treatment can involve dilation and curettage (D&C), laser ablation of endometrial tissue, and hysterectomy. During D&C, the cervix is first dilated (opened wider) and then a curet—a sharp, spoonlike instrument—is inserted through the cervix and used to scoop out the inner lining of the uterus. Laser ablation involves targeted burning of endometrial tissue so that scar tissue forms that does not bleed. Hysterectomy (removal of the uterus), a last-resort treatment, is described later in this chapter.

Nursing Care

The only accurate way to estimate menstrual flow is to weigh used sanitary pads (sealed in a biohazard bag) and then subtract the weight of the original pads. A 1-g increase in pad weight equals approximately 1 mL of blood loss. Simply counting numbers of pads used is much less accurate, because women may change pads at different intervals. You may have to rely on a woman’s report of blood loss. Be sure to document “patient estimate” after the quote.

D&C is typically done as an outpatient procedure. Women can expect some cramping and spotting or light bleeding for a few days afterward.

Dysmenorrhea
Pathophysiology, Etiologies, and Signs and Symptoms

Painful menstruation, or dysmenorrhea, is a common problem in women. Primary dysmenorrhea (menstrual cramps) is not pathological and is thought to be caused mainly by the action of endogenous prostaglandins that stimulate uterine contractions, producing cramping pain. Secondary dysmenorrhea is caused by a reproductive tract disorder such as endometriosis, pelvic infection, retroversion of the uterus, or fibroid tumors.

Diagnostic Tests

Hormonal tests such as estrogen and progesterone levels may be evaluated for primary dysmenorrhea. Additional tests such as laparoscopic examination, biopsies, or cultures may be required for investigation of secondary dysmenorrhea.

</tbody>
</table>
Therapeutic Measures
Primary dysmenorrhea can be treated with drugs that inhibit prostaglandin synthesis, such as aspirin and NSAIDs. Correction of secondary causes of dysmenorrhea may include such measures as hormonal adjustment, usually with oral contraceptives or hormone replacement therapy (HRT), D&C, or other surgical or medical intervention based on the cause.

Nursing Care and Patient Education
Aspirin or NSAIDs help reduce discomfort. A warm heating pad to the abdomen or a hot bath is also helpful. If dysmenorrhea is related to uterine retroversion, assuming a knee-to-chest position may relieve the discomfort. Sudden development of dysmenorrhea in a woman with no previous menstrual discomfort should always be investigated.

Premenstrual Syndrome and Premenstrual Dysphoric Disorder
Pathophysiology, Etiologies, and Signs and Symptoms
Premenstrual syndrome (PMS) is a recurrent problem for many women. Although the exact cause is not understood, ovarian hormones, aldosterone, and neurotransmitters such as monoamine oxidase and serotonin are believed to play a role. Symptoms include water retention; headaches; discomfort in joints, muscles, and breasts; changes in affect, concentration, and coordination; and sensory changes. Few women find PMS serious enough to interfere with work or relationships.

Premenstrual dysphoric disorder (PMDD) is a condition with symptoms of depression, irritability, and tension before menstruation more severe than PMS. Like PMS, the exact cause is unknown. Women with PMDD have at least five of the following symptoms, including one mood-related symptom (PubMed Health, 2012):

- No interest in daily activities and relationships
- Fatigue or low energy
- Feeling of sadness or hopelessness, possible suicidal thoughts
- Feelings of tension or anxiety
- Feeling out of control
- Food cravings or binge eating
- Mood swings with periods of crying
- Panic attacks
- Irritability or anger that affects other people
- Physical symptoms such as bloating, breast tenderness, headaches, and joint or muscle pain
- Problems sleeping
- Trouble concentrating

Therapeutic Measures
A variety of drugs have been given to combat PMS and PMDD with varying degrees of success. Some commonly used medications include drugs that affect prostaglandin production, hormonal balance, and neurotransmitter production and reuptake (such as antidepressants), as well as diuretics and supplements of calcium, magnesium, vitamin E, and vitamin B6. Patients should be warned, however, that dosages of vitamins should not be increased without professional advice because vitamins are medications (as well as nutrients) and high doses of some vitamins can lead to physiological damage. Regular exercise and eating a healthy diet help to reduce symptoms as well.

Nursing Care and Patient Education
Being understanding and nonjudgmental is especially important. Some women who suffer from severe PMS or PMDD may have been treated as if they are psychologically impaired because of the interaction of hormones and neurotransmitters and because of outdated ideas concerning PMS or PMDD. You can help by providing educational materials on lifestyle measures, such as restriction of alcohol, caffeine, nicotine, salt, and simple sugars; participation in regular exercise; and development of stress management skills that may help to reduce symptoms. If the patient is experiencing severe depression, discuss the possibility of suicidal thoughts that can occur with increasing depression symptoms during the second half of the menstrual cycle. Counsel the patient to call 911 or seek medical care immediately if suicidal thoughts occur.

Endometriosis
Pathophysiology, Etiologies, and Signs and Symptoms
Endometriosis is a condition in which functioning endometrial tissue is located outside the uterus (Fig. 42.4). Several theories have been proposed to explain development of endometriosis, including faulty developmental differentiation of cells, transport of endometrial cells via blood and lymph to other parts of the body, and retrograde menstruation—a backward leakage of blood and tissue into the fallopian tubes during the menstrual period.

Endometriotic cells grow in areas of sufficient blood supply, extending into tissues such as intestinal walls, ovaries, and other abdominal structures. On a cyclic basis, mediated by ovarian hormones, these cells build up and slough just as...
they would in the uterus, but the sloughing and bleeding occur in the enclosed abdominal cavity or into the tissues that they have invaded. The buildup of the blood and cells can result in pain, swelling, damage to abdominal organs and structures, scar tissue development, and infertility.

**Therapeutic Measures**

Surgical intervention may be required, especially if scar tissue develops into tight bands that strangle sections of bowel or uterine. Reduction of estrogen and prevention of ovulation either with medications or by surgical removal of the ovaries can be effective but results in infertility and menopausal symptoms. Analgesics may be required for pain.

**Nursing Care and Patient Education**

The severity and persistence of the pain of endometriosis can lead to reliance on pain medication, so it is important to teach patients alternative and complementary pain relief strategies such as relaxation exercises and application of heat to the abdomen or back.

**Menopause**

**Pathophysiology and Signs and Symptoms**

Menopause is the permanent cessation of menstrual cycles resulting from decreased hormone production. This is a natural part of aging, but related uncomfortable symptoms and conditions can occur. The climacteric (perimenopause) is the period of gradual decline in hormone production before the permanent end of menses and may last from a few months to several years. Perimenopausal physical symptoms vary widely and can include erratic menses, atrophy of urogenital tissues with a marked decrease in the amount of natural lubrication, a pH shift toward alkalinity (encouraging yeast overgrowth), and vasomotor instability (resulting in hot flashes and night sweats). Estrogen protects women against several disease processes; the risk of heart disease and osteoporosis increases with declining estrogen production. Mental changes can occur because of the complex interplay of reproductive hormones and neurotransmitters. It is important to acknowledge symptoms such as irritability, anxiety, insomnia, memory problems, and mild depression as a normal, temporary result of hormonal changes, so that perimenopausal women do not doubt their sanity.

**Therapeutic Measures**

Hormone replacement therapy (HRT) is a controversial prevention and treatment for perimenopausal symptoms. Hormone replacement (see Table 42.1 for examples) may be prescribed for severe symptoms and can be administered orally, vaginally, or transdermally. The National Heart, Lung, and Blood Institute of the National Institutes of Health (NIH) conducted a major research project to study the risks and benefits of combined estrogen and progestin therapy for healthy women (NIH, 2002). The project was halted in July 2002, 3 years early, because of very worrisome results. Positive findings included a one-third reduction in hip fractures, a 24% decrease in total fractures, and a 37% decrease in colorectal cancer with HRT. Disturbing findings, however, included a 26% increase in breast cancer, a 41% increase in strokes, a 29% increase in heart attacks, doubling of venous thromboembolism rates, and an overall 22% increase in cardiovascular disease. It is uncertain what to make of these data because there was no difference in total mortality when comparing women treated with HRT and those given a placebo. Long-term results will continue to be examined, but for now, the risks of HRT have been deemed too great to continue the study.

A 2013 Global Consensus Statement now states that benefits of HRT for menopause outweigh risks in some cases, such as in controlling vasomotor symptoms and osteoporosis-related fractures in women under 60 or within 10 years after menopause (deVilliers, 2013). Stay updated on the latest findings at www.nhlbi.nih.gov/health/women.

Dietary changes to include phytoestrogens, which are present in foods and herbs such as soy, tofu, flax seeds, black cohosh, and dong quai, may provide some of the benefits of estrogen replacement without HRT. However, even phytoestrogens have some risk. Women should discuss food and herb supplements with their HCP before using them.

Prevention of osteoporosis begins in early adulthood, long before perimenopause. Fair-skinned white women are at greatest risk for bone loss. Throughout life, adequate intake of calcium and vitamin D (preferably from foods) and regular weight-bearing exercise help to maximize bone mass. At menopause, some women may receive treatment with bone-building medications such as alendronate (Fosamax) to slow bone loss.

**Complications**

It is important to note that resumption of vaginal bleeding after menstruation has finally ceased can be a sign of an endometrial cell disorder caused by either benign changes, such as polyps, or malignant changes of internal reproductive organs. Any bleeding that occurs following previous cessation should always be investigated.

**Nursing Care and Patient Education**

Teach perimenopausal women that they can plan ahead for hot flashes by dressing in layers of clothing that may be removed. Not allowing hot flashes to interrupt activities is an important strategy, as is engaging in satisfying and calming activities that contribute to a sense of serenity. Vaginal symptoms can be treated with a water-soluble moisture restorer or lubricant, or with an estrogen cream (following prescription directions). Eating a healthy diet that is light in caffeine, sugar, and alcohol can help women better control their bodies and minds. Looking forward to new challenges rather than backward to the past may help to counteract hormone-related depressive tendencies. It is important to remind perimenopausal women that...
they may still be fertile even after several months of amenorrhea. To prevent conception, they need to continue to practice birth control until they receive confirmation from their HCP that menopause is complete.

See Table 42.4 for a summary of menstrual disorders.

### CRITICAL THINKING

Lola

- Lola, age 53, has been experiencing menopausal hot flashes during the afternoons as she works in her office.

1. What self-care measures can you suggest to help with her symptoms?
2. If she considers HRT, what information should you share with her?
3. With whom should you collaborate as you help Lola decide what to do?

Suggested answers are at the end of the chapter.

**IRRITATIONS AND INFLAMMATIONS OF THE VAGINA AND VULVA**

Various causative agents can irritate the vulva and the vagina. Signs and symptoms are often similar but there are some differences in the discharge produced in response to the disorders. Table 42.5 lists common vaginal irritations and inflammations that are not generally sexually transmitted. See Chapter 44 for information on sexually transmitted infections.

**Pathophysiology, Etiologies, and Signs and Symptoms**

The normal vaginal environment is a balanced ecosystem with a pH of less than 4.2 as a result of lactic acid and hydrogen peroxide production by cells in the vagina. This acidic pH protects against the growth of many pathogenic microorganisms. A variety of normal resident microorganisms coexist unless the ecological balance is destroyed. Candidiasis, bacterial vaginosis, and cytotolytic vaginitis are all instances of overgrowth of normally present, nonpathogenic microorganisms. Trichomoniasis also is included here because it can be transmitted nonsexually (on fomites, such as toilet seats), as well as sexually, and it grows well when the vaginal environment is disturbed.

Several conditions can predispose patients to an overgrowth of resident microbes: poor nutrition (especially diets high in simple sugars), inconsistent control of blood glucose levels in patients with diabetes, stress, pregnancy, marked hormonal fluctuations, pH changes, prolonged overheating of the genital area with little aeration (as happens with sitting still for long periods in restrictive clothing), and changes in the balance of vaginal flora types because of antibiotic treatment or douching. Patients who have a compromised immune system can experience frequent overgrowth of resident microbes, and, conversely, vaginal infections can make women more susceptible to sexually transmitted infections (STIs), such as gonorrhea and human immunodeficiency virus (HIV). Frequent and persistent yeast infections can be one sign of HIV infection. Vaginosis (overgrowth) and vaginitis (inflammation) can sometimes produce irritation and inflammation in the male sexual partner as well and may lead to urethritis, eczematous changes, and penile inflammation or lesions. A variety of antiinfective medications are used for these disorders (Table 42.6). If the male partner is not also treated, he may reactivate the problem for the woman. Therefore, several types of medication come in “partner packs” for both partners to use.

**Nursing Care and Education of the Patient Undergoing Diagnostic Testing**

The patient may feel embarrassed to talk about what is bothering her. A safe way to begin with most patients is, “Hello.
### TABLE 42.5 COMMON VAGINAL IRRITATIONS AND INFLAMMATIONS

<table>
<thead>
<tr>
<th>Disorder and Etiology</th>
<th>Signs and Symptoms</th>
<th>Discharge/Examination</th>
<th>Diagnostic Tests</th>
<th>Usual Treatment</th>

<td>Avoidance of the offending substance; warm sitz baths or application of hydrocortisone cream</td>
</tr>
<tr>
<td>Atrophic vaginitis: estrogen levels too low to support estrogen-sensitive vaginal tissues</td>
<td>Vulvovaginal irritation, dryness, dyspareunia, increased tendency for resident microbe overgrowth</td>
<td>May have little or increased discharge; discharge may be watery, yellow, or green; may be blood tinged</td>
<td>Maturation index may be determined during Pap test to identify atrophic cellular changes, but diagnosis is usually by history and physical information</td>
<td>Hormone replacement therapy (oral, patch, or vulvo-vaginal cream) or water-soluble lubricant replacing vaginal lubricants</td>
</tr>
</tbody>
</table>

What can I write on your chart as the reason for your visit today?” If embarrassment is evident, a comment that you need to know a bit about what materials to put out for examination purposes often defuses an uncomfortable situation. As you set up materials for a pelvic examination, you can explain that some information is needed to determine how to treat the problem (see Chapter 41). Often this is a good time to ask about vaginal discharge or other signs and symptoms using the WHAT’S UP? format (Chapter 1). Allow the patient privacy while she changes into a gown. Return to the room if requested as a chaperone, assistant, and support for the woman.
### TABLE 42.6 MEDICATIONS FOR IRRITATIONS AND INFLAMMATIONS OF THE VAGINA AND VULVA

</tr>
</tbody>
</table>

**NURSING CARE TIP**

If any wet-mount slides are made, these must be taken to the laboratory immediately while still wet. Use standard precautions to transport samples. Although samples may be taken for culture, the health care provider may prescribe medication before the results return because such irritations are so uncomfortable.

**Nursing Care and Education of the Patient Undergoing Treatment**

Vaginal inflammations and infections may require oral medication or local application of medication in cream, suppository, or medicated douche form. You may apply this for patients who cannot do so themselves, or you may teach patients to self-administer. Anatomically, the vagina slopes back toward the sacrum for about the length of an adult finger (although it can stretch longer). Application is easiest when the patient is lying down ready to sleep because vaginal medications tend to run out when the patient stands or sits. Medicated douches may be administered to a hospitalized patient sitting on a bedpan in bed in semi-Fowler’s position.

Patients may self-administer while sitting on a toilet. Most vaginal medications come with an applicator that either injects a dose of creamy medication or pushes a firmer, shaped dose of medication off the end of the tube when the plunger is depressed. Consult the instructions supplied with the medication. Instruct patients to use all the medication as prescribed and to wear an absorbent pad to prevent possible staining of clothing.

**TOXIC SHOCK SYNDROME**

**Pathophysiology, Etiologies, and Signs and Symptoms**

Toxic shock syndrome (TSS), first identified in 1978, is mainly associated with superabsorbent tampon use during menstruation but can also occur with use of nasal packings, or in other individuals with no specific risk factors. It is a severe systemic infection with strains of *Staphylococcus aureus* that produce an epidermal toxin. The effect of the toxin on the liver, kidneys, and circulatory system makes TSS a life-threatening condition. A streptococcal infection can cause a similar syndrome.

Individuals with TSS may experience a sudden high fever with sore throat, headache, dizziness, confusion, redness of the palms and soles of the feet, rash, blisters, and petechiae, followed by peeling of the skin. Muscle pain and weakness, and gastrointestinal upset have also been reported. Signs and symptoms of TSS should be reported to a HCP immediately.
Prevention
Tampon makers have removed the highly absorbent fibers that were most often associated with the syndrome from their product lines, and TSS is now rare. Women can also reduce their risk of developing TSS by substituting sanitary pads for tampons at least part of the time, such as at night; changing tampons every 4 hours; washing hands carefully before inserting anything into the vagina; not leaving female barrier contraceptives in place for longer than needed; and not using tampons or female barrier contraceptives in the first 12 weeks after giving birth.

Nursing Care and Patient Education
All menstruating women should be taught measures to prevent TSS. They should also be taught to recognize symptoms of TSS because early identification and treatment can save lives.

DISORDERS RELATED TO THE DEVELOPMENT OF THE GENITAL ORGANS

Pathophysiology, Etiologies, and Signs and Symptoms
Several types of congenital malformations of the reproductive organs can affect the health of female patients. Genetic or environmental factors during pregnancy can cause these, and they may require medical or surgical treatment at some point in life. Agenesis of structures means that the y never developed. Hypoplasia of reproductive tract portions means that they are underdeveloped. Imperforate means that expected openings do not exist. Blind pouches exist where cavities should meet but do not. The uterus can form in several configurations, including a double uterus.

Many malformations are discovered during childhood or early adolescence, but some are identified when patients seek medical help because of dysmenorrhea, dyspareunia (pain with intercourse), infertility, repeated spontaneous abortions (miscarriages), or preterm labor during pregnancy.

Diagnostic Tests
Procedures such as ultrasonography, hysterosalpingography, computed tomography (CT), magnetic resonance imaging (MRI), and endoscopy may be used to determine the type and extent of developmental defects.

Therapeutic Measures
Some defects can be repaired surgically; others cannot. Depending on the type and location of the defect, surgeries may be done by endoscopy or by surgical incision. Postoperatively the absence of hormone-producing tissue may be overcome by hormone replacements.

Nursing Care and Patient Education
Patients who have these problems may struggle with self-esteem issues, such as feeling that they are somehow incomplete or have been cheated of something they desire. You can show that you are willing to listen if and when the patient wishes to talk, while allowing her as much privacy as she desires.

DISPLACEMENT DISORDERS

Pathophysiology and Etiologies
The pelvic organs are suspended in the pelvis by ligaments and supported by muscles and fascia. The pubococcygeal muscle runs from the pubis to the coccyx and supplies support from below. Pregnanies (especially those producing large babies) and rapid or traumatic deliveries may result in stretching and injury of the supporting structures, which can cause displacement of the uterus, vagina, bladder, or bowel from a normal position.

The observation that some children have defective muscular support of the pelvic organs and that prolapse is more prevalent in some families seems to suggest that congenital defects and genetic inheritance may also influence displacement disorders even without pregnancy. Scarring from STIs also may be a factor. Aging generally increases the problem because the effects of gravity over time contribute to stretching, and lower estrogen levels weaken estrogen-dependent supportive tissues. Chronic constipation, obesity, and lack of exercise also worsen these problems.

Diagnostic Tests
Ultrasonography, hysterosalpingography, CT, MRI, and endoscopy may be used to determine the type and extent of displacement disorders.

Therapeutic Measures
A pessary is a supportive (usually ring-shaped) device that is placed in the proximal end of the vagina to help support the pelvic organs. A pessary is usually removed daily at bedtime for cleaning, but some types are designed to remain in the vagina for months at a time. When pessary use is begun, it is important that the woman return to the HCP for a recheck after an initial period of use to determine whether it is causing pressure damage to tissues. Because the pessary is a foreign object in the vagina, increased vaginal discharge can be expected. Discharge should not be pink, bloody, or purulent.

Nursing Care and Patient Education
Teach patients to eat a healthy diet to avoid obesity and constipation, and how to do Kegel exercises to keep the pubococcygeal muscle strong and able to support the organs in the pelvic cavity. One way to do Kegel exercises follows:

1. To find the pubococcygeal muscle, tighten while urinating so that the flow of urine stops.

• WORD • BUILDING •
agenesis: a—without + genesis—production
hypoplasia: hypo—little + plasia—shape (or form)
imperforate: im—not + perforate—pierced
dyspareunia: dys—painful or abnormal + pareunia—mating
2. Squeeze the muscle that stopped urinary flow tightly, holding for 10 seconds, and totally relaxing the muscle afterward. Repeat 15 times per day.
3. Practice controlling the muscle by contracting and relaxing it to move the pelvic floor upward and downward very slowly. Thinking of an elevator helps some women. Repeat this 15 times per day.

**NURSING CARE TIP**

Teach women to do Kegel exercises while waiting in lines to use otherwise wasted time to promote their health. Another suggestion is to plan specific times of day or activities that would include Kegel exercises, such as while in a car or working at a computer. Kegel exercises can be done anywhere and are not apparent to anyone watching.

**Cystocele**  
**Pathophysiology, Etiologies, and Signs and Symptoms**

Cystocele occurs when the bladder sags into the vaginal space because of inadequate support (Fig. 42.5A). A feeling of pelvic pressure and stress incontinence are common with this condition.

**Therapeutic Measures**

Kegel exercises or the use of a pessary may help. If these measures are ineffective, anterior colporrhaphy, which is a surgical repair of the anterior portion of the vagina, may be needed. Another possible surgical treatment involves resuspending the bladder.

**Rectocele**  
**Pathophysiology, Etiologies, and Signs and Symptoms**

Rectocele occurs when a portion of the rectum sags into the vagina because of inadequate support (see Fig. 42.5B). A feeling of pelvic pressure, as well as fecal incontinence, constipation, and hemorrhoids, can result.

**Therapeutic Measures**

Kegel exercises can help strengthen the supporting muscles. The patient should maintain bowel regularity with a high-fiber diet to avoid further discomfort and sagging from bowel overdistention. Posterior colporrhaphy may be necessary to correct this problem.

**Uterine Position Disorders**  
**Pathophysiology, Etiologies, and Signs and Symptoms**

The most common variations in position of the uterus are anteversion, anteflexion, retroversion, and retroflexion (Fig. 42.6). In anteversion, the uterus lies too far forward,
and in retroversion, it lies too far backward. In anteflexion, the upper portion of the uterus bends forward, and in retroflexion, it bends backward.

Symptoms that can result from these uterine displacements include painful menstruation and intercourse, infertility, and repeated spontaneous abortion.

**Therapeutic Measures**
A pessary may correct some positional problems. If infertility or recurrent spontaneous abortion is involved or the condition is very painful, surgery to correct the condition may be necessary.

**Uterine Prolapse**

**Pathophysiology, Etiologies, and Signs and Symptoms**

Uterine prolapse occurs when the uterus sags into the vagina (Fig. 42.7). The amount of sagging can vary and can increase over time as a result of the effects of gravity, poor pelvic support, and excessive lifting or straining. In first-degree prolapse, less than half the uterus sags into the vagina. In second-degree prolapse, the entire uterus sags into the vagina. In third-degree prolapse, the uterus sags outside the body.

Uterine prolapse can be very uncomfortable, resulting in back pain, pelvic pain, pain with intercourse (or inability to have intercourse), urinary incontinence, constipation, and development of hemorrhoids. Pressure on the uterus can compromise circulation, resulting in tissue necrosis. Vaginal vault prolapse can also occur in women who have had a hysterectomy, so that the vagina turns inside out and sags downward with similar signs and symptoms. This condition typically requires surgical resuspension.

**Therapeutic Measures**
Some minor uterine displacements may be treated with use of a pessary. Kegel exercises may be more effective in prevention of uterine prolapse than in treatment because, once the tissues become stretched sufficiently for the uterus to sag into the vagina, the continued weight of the uterus prevents adequate contraction of the muscles. Surgery may be done to correct this problem. Although the uterus can be resuspended by shortening the muscles and fascia, hysterectomy is the more common treatment unless further childbearing is desired.

See Table 42.7 for a summary of displacement disorders.

**FERTILITY DISORDERS**

Infertility is a complicated problem with many causes. Some couples with infertility may have multiple reproductive problems. Both male and female partners should be examined. (See Chapter 43 for greater detail on male reproductive system disorders.) Often the woman sees the HCP first and may be given a specimen container and advised to give the container to her partner for provision of a semen sample for analysis. See Table 42.8 for a summary of fertility disorders and diagnostic tests.

### Nursing Care and Education of the Patient Undergoing Fertility Testing

An understanding attitude is very important because infertility can be a cause of low self-esteem, as well as relationship problems. Patients who have been undergoing diagnostic testing or treatment for infertility can become very discouraged with the process and the expense, especially if it has been ineffective. Having to plan your sexual activity around a HCP’s directions can compromise feelings of spontaneity, enjoyment, and privacy. Extensive questioning by nurses can aggravate the situation, but avoiding conversation may convey a lack of caring. A friendly, “Which test shall I help you get ready for today?” may well be enough to get the needed information. Many women undergoing infertility testing are very well informed about the test they will be having and can tell you so that you know which equipment to prepare.

On the first infertility investigation visit, the nurse may teach or give a handout to the patient about keeping a precise record of her oral temperatures with a basal thermometer each morning on awakening, before any other activity. The first day of her menses is day 1 on the temperature chart. Changing levels of hormones result in slight temperature changes, which can be used to identify when ovulation seems to be occurring and when particular hormone levels should be tested. Because many factors can influence temperature and cycles, explain that it may take a few months of recording to clearly identify her pattern.

You may assist with office procedures such as endometrial biopsy, which can be done during a pelvic examination 2 or 3 days before menses is expected. A pregnancy test should be done before this procedure to avoid interfering with a pregnancy. The woman may receive pain medication...
Therapeutic Measures

Treatment of infertility is designed to ensure that an adequate amount of sperm and an ovum can be in proximity in the most conducive environment for fertilization. Removal of barriers such as scar tissue may require surgery. Depending on the results of blood tests and the postcoital test (described in Table 42.8), adjustments of environmental factors may involve such actions as sperm washing to avoid destructive antigen–antibody responses, changing the pH of the seminal fluid to encourage sperm motility, treating the female partner to prevent substances in her genital tract fluids from disabling the sperm, or adjusting her hormone levels. The number of sperm or ovum available can be increased through use of such fertility drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and drugs as clomiphene citrate or various hormone preparations. Infertility treatments are quite complicated and expensive and drugs as clomiphene citrate or various hormone preparations.

Various methods can be used to bring the gametes into proximity. If the problem involves inability to get the sperm close enough to the ovum (as may happen with ejaculatory problems), the HCP may use intrauterine insemination (IUI) to place a semen sample from the male partner closer to the ovum via a small catheter. In vitro fertilization (IVF) involves bringing ovum and sperm together outside the bodies of the participants. Ova may be harvested using a long needle or an endoscope after hormonal preparation of the woman. Sperm can be obtained through masturbation; intercourse with a nonlubricated, nonspermicidal condom; or electrical stimulation of ejaculation for patients with spinal cord injuries. Once fertilized, the ovum is implanted in the woman’s uterus.

For those whose sperm is unable to successfully penetrate the ovum, procedures involving gamete micromanipulation may be done. Under a microscope, an ovum from the female partner is partially opened by removing a portion of the outer covering to facilitate sperm penetration, or sperm may be injected into the ovum. This fertilized ovum is then reinserted into the woman’s body.

When measures to improve the chances of conception using the partner’s own gametes are unsuccessful, gametes from donors may be used. Artificial insemination by injecting another man’s sperm into the woman’s genital tract is the simplest of the donor procedures. Ova also may be harvested from a donor woman and used for in vitro fertilization using the male partner’s sperm if possible. Both of these procedures allow for genetic inheritance from one member of the couple. If genetic inheritance is not possible or desirable (as with familial disease carriers), both donor sperm and ovum may be used for in vitro fertilization to be transferred into the female patient. Surrogacy is a situation in which an embryo from one couple is placed into a “host” mother for growth of a baby for the couple and is a topic of much ethical debate.

Nursing Care and Education of the Patient Undergoing Treatment

Patients who are undergoing infertility treatment may experience many upsetting and distressing feelings. Feelings of inadequacy, frustration, depression, and anger are common. If the infertility was caused by something the patient perceive as avoidable, such as STI, guilt feelings may add to the psychological discomfort. Any or all of the previously described tests may be completed and some repeated many times without success in identifying an underlying etiology for infertility, and may result in repeated disappointments. The beginning of menses may signal a time of mourning for these couples. Depression may result after failed IVF attempts. Strained relationships may develop between marriage partners, especially if there is disagreement about the value of testing or the importance of having children.

In IVF, usually more than the desired number of embryos is implanted because it is expected that not all will survive and because this is more cost effective with less physical risk for the mother. However, this requires heart-wrenching decisions of whether to “reduce” (abort) extra pregnancies or to risk having more than the desired number of children at once as a result of the fertility treatments.

Offer a listening ear while being careful not to give advice about treatment modalities. Researchers and practitioners are engaging in ongoing debate as to the value of particular procedures; consequently, strategies may vary widely from one HCP to another. Encourage open communication among the patient, the HCP, and the patient’s significant other, as well as informed decision making that is based on the patient’s and her partner’s values.

Many varieties of assistive reproductive technology are available, and the number is increasing with research. Most of the procedures are known by their acronyms. For example, GIFT means “gamete intrafallopian transfer” (gametes are placed together in the fallopian tube with the hope that fertilization will occur). ZIFT means “zygote intrafallopian transfer” (fertilization of gametes occurs outside of the body; the conceptus is then placed into a woman’s fallopian tube to make the journey to the uterus). Acronyms can be useful shortcuts but can be confusing to patients. Most nurses probably do not need to know all acronyms or infertility treatments unless the work in a gynecologist’s office or infertility clinic.
Reproductive Life Planning

Reproductive life planning is a more comprehensive term than contraception and implies reasoned decisions related to pregnancy timing and whether or not to have children. Nurses can contribute to the overall health and quality of life for women and families by helping them to find the information they need to make wise choices.

Many types of birth control are available, and several additional types are in developmental and testing stages. General categories of agents are discussed in this section. Understanding of how the different types of contraceptives work can assist the nurse in answering patients’ questions or helping patients find additional information. The World Health Organization (2010) has put together a helpful publication called “United States Medical Eligibility Criteria for Contraceptive Use.” This publication assigns an eligibility category of 1 (no restrictions) to 4 (unacceptable risk of a specific contraceptive method with a specified medical condition) to each contraceptive.

Methods are introduced in the order of usual effectiveness from most to least effective (with the exception that experimental methods are discussed at the end regarding their efficacy). Consult your clinic or HCP for an approved, current comparison list of methods for distribution.

For some patients, the distinction of whether a birth control method actually prevents conception or only interferes with implantation or maintenance of a pregnancy is an important factor in their decision. If a patient believes life begins at conception, any action other than prevention of conception would be considered equivalent to abortion.

Oral Contraceptives

Oral contraceptive medications are among the most widely used forms of birth control in North America. Most contain an estrogen and a progestin in combination, although some (mini-pills) contain only a progestin. Some work to prevent conception by inhibiting ovulation or changing the environment of the reproductive tract so that activity of the sperm is inhibited. Others do not prevent conception but make implantation less likely and hasten the breakdown of the corpus luteum so that pregnancy-sustaining hormones are not produced. Many of the adverse effects that occurred in the past have been overcome by adjustment of dosage levels.

Oral contraceptives can also be used in some instances to regulate irregular menses, decrease menorrhagia or dysmenorrhea, or decrease the symptoms associated with endometriosis or cyclic breast changes. Oral contraceptives do not prevent STIs; advise women about the risks of contracting STIs and using condoms for the prevention of STIs while taking an oral contraceptive.

Advantages, Disadvantages, Side Effects, and Risks

Oral contraceptives are very effective. Improvement of dysmenorrhea, endometriosis, increased regularity of menses, and decrease in menstrual flow may occur; however, some women experience menstrual changes such as amenorrhea, irregular or prolonged menses, and intermenstrual spotting.

Oral contraceptives require a great deal of commitment because irregular use decreases their effectiveness. To encourage regular use, oral contraceptives are generally dispensed in containers labeled with the days of the week, and some companies include unmedicated pills in the package to be taken during the time of hormone cessation for menses, so that the woman only has to remember to take a daily pill, instead of timing the taking of the pills with her cycle. Some oral contraceptives are now available to be taken continuously. Women should speak to their care providers to determine which method is best for them.

Some women experience side effects such as acne, fluid retention, headaches, breast swelling and discomfort, mid-cycle bleeding, and sometimes depression. Use of an oral contraceptive also has some risks. Higher rates of blood clot formation, strokes, high blood pressure, heart attacks, and worsening of diabetes are rare occurrences with some hormonal contraceptives and are generally related to preexisting risk factors. Women who smoke or have diabetes, high blood pressure, heart disease, or a history of thrombophlebitis should receive information about the risks of oral contraceptives and alternative methods of contraception.

Oral contraceptives decrease the risk of endometrial and ovarian cancer, but there is debate about risk of breast cancer and cervical dysplasia (cell changes that may become cancerous) sometimes occurs among oral contraceptive users. Women should definitely be advised to have regular Pap smears while taking oral contraceptives.

Many medications can alter the effectiveness of oral contraceptives, and women should be warned to always alert HCPs and pharmacists that they are using oral contraceptives when a new medication is started or a regular medication is discontinued. Use of hormonal contraceptives increases the risk of vitamin B deficiencies, so a healthy diet with good sources of B vitamins is advisable.

LEARNING TIP

Side effects of oral contraceptives can be serious. Teach your patient to watch for “ACHES” and to contact her primary care provider immediately if they occur. ACHES stands for:

- Abdominal pain
- Chest pain
- Headache
- Eye pain
- Severe leg pain

WORD BUILDING

contraceptive: contra—against + ceptive—taking in (conceiving)
dysplasia: dys—painful or abnormal + plasia—shape or form
Chapter 42 Nursing Care of Women With Reproductive System Disorders

Contraceptive Implant and Injectable Medications

Contraceptive implants are small permeable tubes surgically implanted through a small incision under the skin; they slowly release hormones for long-term contraception. Implants have been used with varying success; an example is etonogestrel implant (Nexplanon).

Medroxyprogesterone acetate (Depo-Provera) is a contraceptive agent available in a slow-release depot form that can be injected intramuscularly. Medication is continuously released for 3 months.

Advantages, Disadvantages, Side Effects, and Risks

The main advantage of depot medications and implants is that the woman does not have to remember to take daily medication. Disadvantages are that the medications may not be immediately effective, so another method may be necessary for 1 to 2 weeks after the initial injection, and that fertility may not return for several months to 1 year after discontinuation.

Alterations in menstrual flow, especially amenorrhea, are the most commonly noted side effects with both depot medications and implants. Weight gain of 5 to 10 pounds is also common, which can lead to discontinuation of use. Other side effects and risks are similar to those encountered with oral contraceptives that contain progesterone only.

Estrogen-Progestin Contraceptive Ring

A newer method is an estrogen-progestin contraceptive ring (NuvaRing). It works in much the same manner as other hormonal contraceptives by slowly releasing hormones. The user inserts the ring into the vagina. The ring is left in place for 3 weeks; it is then removed for 1 week in order for menses to occur, after which a new ring is placed.

Advantages, Disadvantages, Side Effects, and Risks

Not having to remember daily medication can be an advantage to the contraceptive ring, but failing to remove it at the right time may disrupt the regularity of the menstrual cycles. With consistent use, it is very effective in preventing pregnancy. Because it does not provide a barrier over the cervix, there is less risk of infection than with a diaphragm or cervical cap. A common side effect is an increase in normal vaginal discharge. Other side effects and risks are similar to those encountered with oral contraceptives.

Transdermal Contraceptive Patch

A transdermal patch is now available that contains norelgestromin and ethinyl estradiol (Ortho Evra). It is placed on the abdomen, upper arm, or buttock after a menstrual period and left in place for 1 week. A new patch is placed on the body each week for 3 weeks. After 3 weeks, the patch is removed and not replaced for 1 week in order for menses to occur.

Advantages, Disadvantages, Side Effects, and Risks

The contraceptive patch has been found to be similar to oral contraceptives in effectiveness, side effects, and risks, without having to remember to take a pill each day. The patch will remain in place during bathing, swimming, and other activities.

Barrier Methods

Barrier methods of birth control are less effective in preventing pregnancy than most of the previously mentioned methods when used alone. Barriers are intended to prevent sperm from reaching the ovum. Used in combination, the effectiveness of barrier methods with spermicidal preparations comes close to that of oral contraceptives. Both may be purchased without a prescription.

Condoms

Condoms are barriers that are used once and then discarded into an appropriate waste receptacle. Most condoms come with spermicide/nonoxynol-9. Condoms used with contraceptive jelly or spermicide are most effective at decreasing risk of pregnancy. They should be stored in a cool, dry place before use and should not be stored where heat and continued pressure can weaken them. Storage in a wallet or glove compartment is not advisable. Petroleum-based substances, such as Vaseline, can also weaken condoms, so use of water-soluble lubricants (preferably spermicides) should be advised.

ADVANTAGES, DISADVANTAGES, SIDE EFFECTS, AND RISKS OF MALE CONDOMS. Male condoms have long been used for contraception because they are a relatively inexpensive, totally reversible method that men can control at the time of intercourse. They also provide some barrier protection against transmission of STIs. An electron microscopic study of a sample of nonlubricated latex condoms, however, found that most of those viewed had surface abnormalities, including cracking and melted areas. Patients should be informed that barrier methods can reduce risk but do not absolutely prevent transmission of STIs, especially in areas of contact not covered by the barrier.

The main disadvantages of condom use are interruption of foreplay for application, decreased sensation, and the possibility of slippage or breakage during intercourse. These disadvantages may be overcome by incorporating application of the condom by the female partner as a part of foreplay; using thinner, lubricated, or textured condoms to increase sensation; using the correct size condom with a reservoir or application that leaves about a half-inch at the tip of the condom loose enough to serve as a reservoir for semen (Fig. 42.8); and removal from the vagina before relaxation of the erection.

ADVANTAGES, DISADVANTAGES, SIDE EFFECTS, AND RISKS OF FEMALE CONDOMS. Female condoms are a more recent innovation that allows female initiation of contraception, as well as some barrier protection against STIs. Coverage of the labia by the condom may provide more of a barrier than male condoms (Fig. 42.9). Disadvantages are similar to those of male condoms; they are also more expensive than male condoms.

Diaphragms and Cervical Caps

Diaphragms and cervical caps work in the same manner as condoms, by blocking the entry of sperm through the cervix (Fig. 42.10). The barrier effect is enhanced by simultaneous...
use of a spermicide. Application of a spermicide to the edge of the device and placement of a small amount in the cup before use increases effectiveness.

**ADVANTAGES, DISADVANTAGES, SIDE EFFECTS, AND RISKS.** These methods are relatively inexpensive, are female initiated, and work without systemic medication. Diaphragms and cervical caps require initial fitting and a prescription to buy them, may need to be refitted after childbirth and the loss or gain of weight, and can last for years. They should be replaced periodically based on manufacturer recommendations or whenever there is any evidence of hardening, cracking, or thin spots. They need to be washed with soap and water, dried, and stored in a case away from heat and sunlight between uses.

Women and their partners can experience irritation or allergic reaction to the spermicide or the contraceptive device material, which would require changing birth control methods. These types of methods require that the device be inserted before intercourse and left in place for several hours afterward. (See package inserts for specific recommendations.) An increase in incidence of urinary tract infection has been reported with use of the diaphragm, and risk of TSS increases with prolonged uninterrupted use of cervical barriers. Adequate fluid intake, voiding shortly after intercourse, and removal of the device as directed following intercourse all help to prevent these potential problems. If urinary tract infections are recurrent using the diaphragm, changing to a cervical cap may decrease the occurrence because there is less pressure against the bladder through the anterior vagina.

**Spermicides**

Spermicidal agents may be used alone, although use in combination with a barrier method is much more effective. They come in a variety of forms, such as creams, gels, foams, and suppositories, which kill or disable sperm so that fertilization does not occur.

**Advantages, Disadvantages, Side Effects, and Risks**

Spermicidal preparations are relatively inexpensive and can be male or female initiated. They do not produce systemic effects, and no hormones are involved. Spermicides require application before each act of intercourse and some patients
consider them to be somewhat messy. Many contain the same ingredient—nonoxynol 9. If genital irritation or a rash occurs with a spermicide, the patient should read labels carefully to avoid future contact with the same ingredient.

Intrauterine Devices

The presence of a foreign object in the uterus is thought to alter the environment so that implantation is less likely to occur. IUDs are generally made from a form of plastic and may contain copper wire (such as the ParaGard) or a supply of a progestin (for example, Mirena) that is slowly released into the system to further alter the uterine environment to hinder fertilization or implantation.

Advantages, Disadvantages, Side Effects, and Risks

The main advantage of an IUD is continuous contraception without the necessity of remembering to take medication and without the side effects associated with medications. The ParaGard is effective for 10 years, and the Mirena is effective for 5 years. Mirena may help lighten and potentially eliminate menstrual bleeding in women who have a history of anemia or heavy menstrual flow.

Disadvantages are changes in menstrual bleeding, cramping, and increased risk of pelvic inflammatory disease (PID). Rarely, an IUD has caused a uterine perforation. New research and changes in the medical eligibility criteria set up by the World Health Organization has shown that IUDs can be used by women who have never been pregnant because advantages far outweigh risks. IUDs should be avoided in women with uterine abnormalities, those with PID, and those who have current STIs. Expulsion or displacement of the IUD can occur, so women should be taught to feel for the presence of the external string before intercourse.

Insertion Procedure

Insertion of an IUD typically is done in a HCP’s office, usually during the first 7 days of the menstrual cycle because the cervix is slightly dilated at this time. The IUD is inserted into the cervix through a tube that comes packaged with the IUD, which temporarily holds the IUD flat or folded for insertion. When the IUD is pushed out the end of the tube, it springs into a shape that helps to keep it inside the uterus. One potential danger of IUD insertion is vasovagal reflex stimulation (previously described in association with endometrial biopsy). Periodically assess pulse or blood pressure during the procedure and notify the HCP of slowing of the heart rate or a decrease in blood pressure.

Natural Family Planning

Periodic abstinence (natural family planning) is less effective than the previously described methods. It is a method by which couples control their fertility by restricting intercourse to “safe periods” during which risk of conception is low. Many signs can be assessed to determine “safe” days, including temperature changes, cervical consistency and mucus changes, calendar timing, and awareness of symptoms of fertility.

Slight body temperature changes can indicate ovulation. During the first half of the menstrual cycle, the temperature remains low, with a marked drop just before ovulation occurs. With ovulation the temperature rises and stays higher for the last half of the cycle. Women who use this assessment method should use a basal body temperature thermometer when they awaken, before doing anything else, and record it on a chart.

Cervical consistency and mucus changes can also help pinpoint ovulation. As hormone levels change, the consistency of cervical mucus changes. As ovulation approaches, there is an increase in the amount of mucus and the mucus becomes more clear, thin, slippery, and stretchable than at other times of the month. Around the time of ovulation, the cervix becomes softer to touch and more open than at other times of the cycle.

Following the calendar can work fairly well if a woman’s menstrual periods are regular, but becoming aware of her pattern may take time. Symptoms such as breast tenderness and midcycle discomfort (mittelschmerz) can also help identify ovulation. Users of this method should be advised to abstain from intercourse for approximately 3 days before ovulation and 3 to 4 days after because the sperm and ovum can survive for a long period in the female genital tract.

Advantages and Disadvantages

The advantages of this method are that it requires no expense or medication, and it is the only birth control method currently approved by the Catholic Church. The disadvantages are that it requires the cooperation of both partners and may interfere with spontaneity of sexual expression. It is generally
not very effective as a means of birth control. It may be difficul
to accurately identify ovulation times because infec
tious and inflammatory processes can affect temperature
readings, infections and feminine hygiene products can affect
cervical mucus, and irregularity of flow and symptoms may
make prediction difficult.

Less Effective Methods

Coitus Interruptus

Coitus interruptus involves removal of the penis from the
vagina before ejaculation occurs.

ADVANTAGES, DISADVANTAGES, AND RISKS. Although this
method requires no expense or preparation, it is not very effective.
Excellent control of ejaculation is required, and even the
small amount of sperm that may be present in pre-ejaculatory
fluid can result in pregnancy.

Postcoital Douching

The intended purpose of postcoital douching is to wash sperm
out of the reproductive tract or to kill or immobilize sperm
that the douche solution contacts.

ADVANTAGES, DISADVANTAGES, AND RISKS. This is rela
tively inexpensive and female initiated, but it is not very effective.
Sperm move very rapidly once deposited, and douching may actually push the sperm upward.

Lactational Amenorrhea Method (Breastfeeding)

Breastfeeding is sometimes used as a method of birth control
because the high blood levels of prolactin that occur with breast-
feeding may suppress ovulation. This may be effective in the
first 6 months after delivery and requires “full or nearly full”
breastfeeding, and that the woman has not experienced her first
postpartum menses (any bleeding 56 days postpartum).

ADVANTAGES, DISADVANTAGES, AND RISKS. This method
costs nothing but is not very effective. Prolactin levels can vary widely, and ovulation may resume at any time without any noticeable signs, resulting in pregnancy before even experiencing a menstrual period after the birth.

Ongoing Research: Future Possibilities

for Contraceptive Choices

Many researchers have tried to develop effective and re
versible male contraceptives. When taken orally a plant called
Tripterygium, used in Chinese herbal medicine, yields sub
stances that can limit numbers and mobility of sperm, but it
also has ingredients that suppress immunity somewhat, so
further investigation is necessary. Reversible injection proce
dures to block the seminal vas deferens are also being inves
tigated, as are reversible injection procedures to block the
fallopian tubes. Reversible birth control vaccines are also
being investigated for both men and women with the goal of
caus ing an immune response to occur at some vital point in
the process of conception.

Some questions related to contraceptive vaccines include
the unknown long-term repercussions of stimulating the body
to respond with immunity to itself and whether governments
could use vaccines as a means to control populations without
individuals’ consent. Another frightening possibility is that
with further removal of the threat of pregnancy, even fewer
people would use barrier methods, and STIs would increase.

CRITICAL THINKING

Jessica

- You have just observed a patient who appears to be
  about 13 years old announce loudly at the clinic recep
tion desk that she is “ready to be a responsible adult”
  and would like some birth control.

1. What information should be gathered from her?
2. What do you think she needs to know before mak
ing a decision?
3. How can you base your teaching on her desire to be
  a responsible adult?

Suggested answers are at the end of the chapter.

Sterilization

Permanent sterilization can be accomplished by either inter
rupting the fallopian tubes or vas deferens (by vasectomy, as
discussed in Chapter 43) or by removing the uterus (hysterectomy).
Tubal interruption may be done by tying a suture or placing a
ring or clip around each fallopian tube, by coagulating a section of
the tube, or by surgically removing a portion of the tube and suturing the ends. These procedures are
usually done by laparoscopy in an outpatient setting, as an
additional procedure performed after vaginal delivery. A new nonsur
gical procedure (Essure) uses an endoscope to implant a tiny
insert into each fallopian tube to block patency.

Advantages, Disadvantages, Side Effects,
and Risks

Although sterilization is not absolutely certain to be perma
nent, the failure rate is low and has been decreasing recently
with newer surgical methods. After vasectomy, men must re
turn to the HCP’s office to supply at least two semen samples
to ensure no sperm are present. Reversal is sometimes re
quested at a later time to reestablish fertility. This requires
microsurgery with anesthesia and has a poor success rate.

Patient Education

Patients should be advised by their surgeon about the com
plications of the surgery and reversal before they sign a con
sent form for sterilization. If an uncertainty about the
surgery is evident, the HCP should be notified promptly.

PREGNANCY TERMINATION

Termination of pregnancy (abortion) is a difficult topic. Dis
cussions about it are often highly charged with emotion. Both
Chapter 42  Nursing Care of Women With Reproductive System Disorders  993

prolife and prochoice advocates argue on the basis of human rights—the former based on rights of the fetus and the latter on rights of the mother—because of the humanity of each party. There are few people on either side of the philosophical argument, however, who would describe abortion as a healthy medical intervention. Most agree that abortion is a problematic solution to a difficult situation.

Types of Abortion

Therapeutic Abortion for Ectopic Pregnancy
An ectopic pregnancy is the implantation of a fertilized ovum in an area other than the uterus. This can occur because of an abnormally shaped uterus or fallopian tubes that are obstructed as a result of abnormal development, scarring from STIs or other inflammatory processes, or for unknown reasons. It is a life-threatening situation for the mother and currently a therapeutic abortion is the only treatment.

Therapeutic Abortion for Prenatal Abnormalities

Development of a variety of prenatal testing methods has introduced the possibility of knowing many things about a baby before birth. Prenatal testing may be done using ultrasound, samples of fluid taken from the amniotic sac or the placental villi, or blood samples from the mother. From these tests, some genetic diseases and congenital deformities can be identified. After anomalies are diagnosed, some patients choose to abort the baby. This is a very difficult decision to consider even in instances in which the baby has a fatal defect that will not allow it to live outside the uterus. It is important to provide information about alternatives to abortion and possible treatments for their child when a patient has a serious prenatal diagnosis. No one should feel pressured to make the decision quickly to abort, but legal requirements and increasing risk for the mother may limit the time to decide. Abortion because of fetal abnormality may result in much grieving and guilt for the patient and her family.

Methods of Abortion

Several methods are available. The method is determined primarily by the length of the gestation and the goal of inflicting as little trauma to the mother’s reproductive system as possible while still inducing pregnancy loss. Time periods for the different abortion methods and the allowable reasons for legal abortion vary according to the laws of the state, province, or country.

Chemical Agents

Emergency contraception, known as Plan B, is sometimes called the “morning-after pill.” Treatment consists of postcoital administration of sufficient estrogen/progestin (levonorgestrel) to prevent ovulation and possibly to prevent fertilization if ovulation has already occurred. The drug also prevents a fertilized ovum from implanting in the uterine lining. If a fertilized ovum has already implanted when the patient takes the drug, the pregnancy will not be terminated. For this reason, there is some disagreement about whether Plan B is a form of contraception or a form of abortion.

Plan B is available at pharmacies without a prescription. Typically, it is used after unexpected, unprotected sexual intercourse (as with sexual assault) or with unexpected risk of conception (as with condom failure). For the medication to be effective, the initial dose typically is given within 72 hours after intercourse and preferably within the first 24 hours. Because no advance planning is required before intercourse, Plan B can be misused as a casual form of birth control. Patients who use it in this way need education about more appropriate birth control methods. Side effects of Plan B can include nausea, vomiting, headaches, and breast tenderness.

Another type of postcoital medication prevents the binding of progesterin at their receptors, which causes a chemically induced abortion up to the 10th week of pregnancy. This is known as a medical abortion. Medication can be given orally and/or vaginally. You may recall the controversial RU-486 (mifepristone, marketed under the name Mifeprex). Mifepristone causes the blockage of progesterone from the uterine lining, causing the lining to break down. The patient is also then given a dose of misoprostol, which causes the uterus to empty. It must be used within 63 days after the first day of the woman’s last period. Pregnancy must be confirmed along with how far pregnant a woman is before medical abortion. Nausea and cramping can accompany expulsion of the uterine contents.

There is much debate about whether mifepristone should be used at all or only within specific guidelines. The U.S. Food and Drug Administration approved mifepristone in 2000 in an accelerated drug-approval process, but legislative bills have been repeatedly introduced to stipulate prescribing regulations for HCPs. Undoubtedly mifepristone, as well as methotrexate (a chemotherapy medication) and misoprostol (a medication to prevent stomach ulcers), all of which can stimulate abortion, will continue to be the subject of much debate.

Abortion Methods for Early Pregnancy

Early in pregnancy (during approximately the first 13 weeks), there are three primary means of pregnancy termination: menstrual extraction, vacuum aspiration, and D&C. Menstrual extraction is removal of the endometrial lining by manual suction and can be done during the first 7 weeks following the last menstrual period (LMP). This can be done without anesthesia and without cervical dilation by inserting a small cannula into the cervix and aspirating with a lage syringe. Vacuum aspiration is a similar process that is used from confirmation of pregnancy through the first 13 weeks. It requires cervical dilation and usually is done with local anesthesia. The patient returns home 1 to 4 hours after the procedure. D&C also may be used during the first 13 weeks. In this procedure, the cervix is dilated and the uterine contents are scooped away with a curet. This is done as an outpatient procedure under general, regional, or local anesthesia.

Abortion Methods for Later Pregnancy

During the second trimester, the fetus is much larger, so more dilation is required. A dilation and evacuation (D&E) may be performed in much the same manner as a D&C. Dried laminaria (a type of sea weed) or some other absorbent
substance is placed inside the cervical canal. This absorbs fluid and swells, thus gradually dilating the cervix. Prostaglandin may be administered either by suppository into the vagina or by injection into the amniotic sac; this usually induces uterine contractions and results in delivery a few hours later. Unfortunately, a live fetus too premature to survive may be born by this method and continue to breathe for a time until death.

An induction with either a saline or urea injection may be used for pregnancies beyond 16 weeks. A portion of amniotic fluid is removed and replaced with concentrated saline or urea solution, which kills the fetus and stimulates contractions. Sometimes saline and prostaglandins are used in combination to terminate a pregnancy.

**Hysterotomy** involves removal of the uterine contents through an abdominal incision in the same manner as a cesarean delivery. This procedure is rarely done for pregnancy termination.

**Risks and Complications**

Abortion involves risks. Some are the same risks inherent in childbirth, such as possible hemorrhage or introduction of infection, but there are additional risks related to the interruption of natural processes and the aggression with which the products of conception are removed during abortion. During an uncomplicated childbirth, the uterine lining is not scraped or forcefully emptied by suction. Natural hormonal preparation for term childbirth contributes to uterine contraction after the birth, which decreases blood loss, but no such preparation occurs for abortion. Artificial dilation of the cervix may cause injury, as may introduction of the instruments used for abortion. Injured tissues can become sites for growth of microorganisms. Finally, the possibility of infertility as a result of complications related to abortion, although relatively uncommon, is a risk.

Some possible physical complications following therapeutic abortion are injuries to the uterus or cervix, excessive bleeding, infection, retention of some products of conception, and possible failure of abortion. Rarely, second-trimester abortions can be complicated by amniotic fluid embolism, in which amniotic fluid is absorbed into the uterine circulation because of disruption of placental attachments with instruments. Amniotic fluid in the mother’s circulatory system can result in circulatory collapse and disseminated intravascular coagulation (DIC). DIC is a serious derangement of the body’s blood clotting controls and, although rare, can be fatal.

**Nursing Care and Patient Education**

Care after abortion is very important. Patients rarely stay overnight, and complications can occur after they are discharged. Patients should be carefully assessed after the procedure for signs of bleeding. Instruct the patient that bleeding should not exceed that of a heavy period, that the passage of clots larger than a quarter may be a sign of complications, and that the discharge should not become foul smelling. Patients should be given a phone number to call 24 hours per day, 7 days per week if fever, chills, excessive bleeding, or foul-smelling discharge occur. The patient should be advised to abstain from sexual intercourse for the time specified by the HCP (usually about 3 weeks).

A grief response may occur after a pregnancy termination, even if the baby was unwanted and the patient does not have strong beliefs against abortion. There is debate about frequency of postabortion syndrome or whether such a condition exists. However, loss and trauma have occurred in any case, and reorganization of the self takes time. Availability of psychological counseling for women after abortion is very important. Women should be given a number to call if they experience psychological discomfort. The need for birth control should be assessed.

**Ethical Issues**

Ethically, an individual nurse should not be required to assist in any treatment that demands he or she act in a way that contradicts personal moral beliefs. This would violate the nurse’s rights. However, there is also an ethical duty to provide care to patients for whom the nurse is responsible. Therefore, it is wise for nurses who have moral objections to abortion to carefully choose their work setting. For example, choosing to work in day surgery in a hospital that performs abortions and refusing to care for abortion patients is not a legitimate option (see “Ethical Considerations” on DavisPlus). One way nurses can positively influence the abortion situation is by teaching about family planning, which may lower the number of requests for abortions. Another way might be to become involved with agencies that help pregnant women find viable alternatives to abortion.

---

**TUMORS OF THE REPRODUCTIVE SYSTEM**

**Benign Growths**

**Fibroid Tumors**

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Fibroid tumors, or leiomyomas (plural form is leiomyomata), are benign tumors made up of endometrial cells that have implanted on or within the walls of the uterus. These can grow very large and may cause pain or menstrual disorders, exert pressure on the bladder or bowel, cause necrosis because of pressure on the blood supply to tissues, and interfere with fertility. Although the exact cause is unknown, heredity and hormones play a role.

**THERAPEUTIC MEASURES.** Because fibroid tumors are estrogen sensitive, medical treatment may involve hormone suppression. Uterine artery embolization (also called fibroid embolization) involves introduction of tiny sponge-like particles into the artery that supplies the fibroid. This cuts off the blood supply to the tumor and causes it to shrink. Sur gical options include myomectomy or hysterectomy. Myomectomy is re-
moval of only the fibroid tumor and may be chosen to preserve fertility. Myomectomy may be done surgically through an abdominal or vaginal incision or with a laser introduced through a laparoscope. Hysterectomy may be necessary for very large fibroids or those that cause severe bleeding or discomfort.

**Polyps**

**PATHOPHYSIOLOGY, ETIOLOGY, AND SIGNS AND SYMPTOMS.** Polyps are benign growths that grow inside the uterus or on the cervix and may bleed after intercourse or between menstrual cycles. They are generally teardrop shaped and are attached by a stalk. Polyps develop most often after age 42. The cause is unknown, but estrogen plays a role in their development.

**THERAPEUTIC MEASURES.** Polyps are generally removed vaginally or transcervically by separating the stalk from the uterus and then stopping the bleeding by use of chemical, electrical, or laser cauterity. Removal of polyps in the vagina can be done without anesthetic in an HCP’s office. Removal of polyps transcervically requires cervical dilation and is more likely to be done in a hospital with anesthesia.

**Reproductive System Cysts**

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Several types of cysts can affect women’s health. Cysts of the ovaries can develop associated with incomplete ovulation, hypertrophy of the corpus luteum after ovulation, or inflammation of the ovary. Most ovarian cysts will eventually shrink spontaneously and merely cause discomfort for a time. “Chocolate” cysts are formed when endometrial cells bleed into an enclosed space, as occurs with endometriosis. They are called chocolate cysts because they are filled with old blood that has become chocolate colored. Cystoadenomas are benign growths that can sometimes undergo cellular transformation and become cancerous. Any pelvic mass in a postmenopausal woman should be investigated for malignancy.

**THERAPEUTIC MEASURES.** Most cysts are not surgically removed, but excessive size, interference with fertility, and high cancer potential may make needle drainage, biopsy, laparoscopic surgery, or laparotomy advisable. If cysts are painful, application of heat to the abdomen or back can help promote comfort.

**Polycystic Ovary Syndrome**

**PATHOPHYSIOLOGY AND ETIOLOGY.** Polycystic ovary syndrome (PCOS) is a complex abnormality of endocrine balance of unknown etiology. Multiple cysts on the ovaries are a sign that was discovered early and for which the disease was named, but they are not present in all cases. There seem to be strong genetic links with such familial history as too much or too little hair (especially for women), severe acne, diabetes, irregular menses, and infertility. Many of the symptoms of PCOS are a result of insulin resistance with excessive levels of insulin in the blood, which in turn stimulates secretion of androgens.

**SIGNS AND SYMPTOMS.** Women with PCOS often have infertility, obesity, and menstrual disturbances. They also may have masculinization because of the excess androgen secretion. They have an increased risk of diabetes mellitus, elevated blood pressure, coronary artery disease, and endometrial cancer.

**DIAGNOSTIC TESTS.** Diagnostic tests can include blood tests to rule out other causes of endocrine abnormality tests to determine whether ovulation is occurring (such as midluteal progesterone levels and basal body temperature graphing), endometrial biopsies to determine the level of proliferation and to check for endometrial cancer, and blood tests to determine lipid levels and glucose tolerance.

**THERAPEUTIC MEASURES.** Medical treatments can involve blood pressure medications, lipid control medications, and oral hypoglycemic agents such as metformin (Glucophage). Diet and exercise may be recommended for weight reduction, control of lipid levels, and cardiac health. Oral contraceptives may be used to normalize hormone levels and protect the endometrium for those not desiring to conceive. Ovulation-inducing medication may be used for women who desire to conceive; treatment with metformin may also prompt ovulation.

If masculinization is a problem, antiandrogen medication such as spironolactone (Aldactone) may be prescribed. In severe cases, gonadotropin-releasing hormone (GnRH) agonists may be used to produce medical suppression of the ovaries, with results similar to removal of the ovaries. This is followed 6 months later with an estrogen-progestin combination to protect the bones from osteoporosis.

**Bartholin’s Cysts**

**PATHOPHYSIOLOGY, ETIOLOGY, AND SIGNS AND SYMPTOMS.** Bartholin’s cysts are actually infected Bartholin’s glands at either side of the vaginal opening that occur due to obstruction of the glands. Excessive swelling of Bartholin’s glands results in pain with sitting and with intercourse.

**THERAPEUTIC MEASURES.** Incision and drainage can alleviate the discomfort. If Bartholin’s cyst formation occurs often, marsupialization—the surgical formation of a pouch around an opening made into a gland to facilitate drainage—may be needed. Sitz baths may be ordered to cleanse the area and to promote comfort and healing.

**Dermoid Cysts**

**PATHOPHYSIOLOGY, ETIOLOGY, AND SIGNS AND SYMPTOMS.** Rarely and for unknown reasons, a dermoid cyst (also called a cystic teratoma) may develop from a germinal...
cell of an ovary. This cell divides and differentiates into various tissue types such as skin, teeth, bones, hair, and even extremities in a disordered arrangement. This type of cyst may grow quite large and may occur on both ovaries at the same time.

**THERAPEUTIC MEASURES.** Dermoid cysts are removed by laparoscopy or laparotomy. If the cyst contains glandular tissue that is secreting hormones, adjustment of hormone levels to normal may take some time. Although most teratomas are benign, some are malignant, especially in postmenopausal women, so a biopsy is generally done on the tissue.

**NURSING CARE AND PATIENT EDUCATION.** Growth of a dermoid cyst can be a frightening experience for a woman. Reassurance that this is a disordered group of cells identical to the other cells in her body, rather than a deformed baby, is important.

### Malignant Disorders

It is difficult to distinguish benign growths from malignant growths without biopsy results, and some benign growths can become cancerous. Malignancies can occur in all parts of the reproductive system and at all ages. Although reproductive system cancers are more common in older age groups, ovarian tumors can occur even in young children. Both male and female children of women who were given diethylstilbestrol (DES) in the past to prevent premature delivery in high-risk pregnancies have experienced a high incidence of developmental defects and cancers of the reproductive organs.

This section presents a general overview of the most common cancers. If investigated and treated early enough, cure is often possible.

#### LEARNING TIP

“Three C” changes that may indicate cancer are changes in color, contour, and consistency of a tissue.

### Vulvar Cancer

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Although vulvar cancer is not common, alertness to changes in visible parts of the reproductive system such as the vulva can result in early diagnosis, requirement of less drastic treatment, and end with more positive results. Persistent itching of the vulva or appearance of white or red patches, rough areas, skin ulcers, or wartlike growths should not be ignored; these can be signs of precancerous or cancerous changes. Risk factors for development of vulvar cancer are having an STI of any type, precancerous or cancerous changes of the anus or any of the genitalia, immune system depression, and smoking.

**DIAGNOSTIC TESTS.** Regular Pap smears and physical examinations can identify lesions. Biopsy of suspicious lesions is necessary to diagnose vulvar cancer.

**THERAPEUTIC MEASURES.** If discovered early, vulvar cancer may be treated with removal or destruction of cancerous cells. If not diagnosed early, it may require surgical removal of the entire vulva and associated lymph nodes (a radical vulvectomy) with subsequent skin grafting from other areas of the body for repair.

### Cervical Cancer

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Changes in cervical cells seen with a Pap smear are called cervical dysplasia. Abnormal cells are most often caused by human papilloma virus (HPV). If abnormal cells are found on a biopsy of the cervix, then it is called cervical intraepithelial neoplasia. Without treatment, severe dysplasia can turn into invasive cancer. The severity of the dysplasia determines the treatment plan.

Some identified risk factors for development of cervical cancer include starting sexual activity at an early age, having multiple sexual partners, having several pregnancies, smoking, and being infected with HPV or herpes simplex virus type II (HSV-II). Use of oral contraceptives may also increase a woman’s risk of developing cervical cancer, although some of the increase in incidence may be because women using oral contraceptives may not be using barrier protection against STIs. Although some women experience slight spotting or serosanguineous discharge with cervical cancer, many are asymptomatic until the cancer is widespread.

**DIAGNOSTIC TESTS.** Pap smears are the best method of screening for cervical cancer currently available, but some work is being done on self-tests that women can collect. A Pap smear determines the degree of cellular change, or dysplasia. Ranking systems vary, but Pap smear results are usually presented in categories that range from no atypical cells seen to invasive cancer evident (0 to IV). This procedure has significantly reduced the incidence of invasive cervical cancer over the years since its introduction because cellular changes can be identified early enough for treatment to begin before the cells become cancerous. Colposcopy is done to obtain more information following an abnormal Pap smear (see Chapter 41). New guidelines introduced in 2012 recommend Pap smears starting at age 21 and then every 3 years unless abnormalities develop (American Cancer Society, 2012). After a period of normal Pap smears, some HCPs advocate longer intervals for low-risk women.

**THERAPEUTIC MEASURES.** Treatments for preinvasive neoplasia include cryotherapy (freezing), laser therapy (burning), and surgical removal of the involved area with a loop excision instrument or by conization (Fig. 42.11). All of these procedures are done through the vagina, so there are no external incisions. After any of these treatments, the patient is advised not to douche, use tampons, or have intercourse for approximately 2 weeks to allow healing to take place. She should be advised to report immediately if fever,
bloody vaginal discharge, or foul-smelling vaginal discharge occurs. For invasive cancers, hysterectomy, radiation implant, or chemotherapy may be done.

**PREVENTION.** In 2006, a vaccination to help protect against HPV types 6, 11, 16, and 18 was introduced, known as Gardasil (human papillomavirus vaccine). Although there are many high-risk types of HPV, types 6 and 11 cause 90% of genital warts and types 16 and 18 cause 70% of cervical cancers. The vaccination is recommended for both males and females ages 9 to 26, regardless of sexually activity status or exposure to HPV. The vaccination consists of three injections over a 6-month period. The vaccination is still being studied for its longevity.

**Endometrial Cancer**

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Endometrial cancer is the most common type of uterine cancer. Most develop in response to relative estrogen excess. Abrupt changes in bleeding patterns, especially bleeding in a menopausal woman, can indicate endometrial cancer development. Estrogen excess can develop for many reasons. Estrogen levels fluctuate widely in the perimenopausal period. Obesity results in increased estrogen production that is not balanced by progestins. Estrogen replacement therapy for menopausal symptoms without the addition of progestins also has been associated with an increase in endometrial cancer, but addition of a progestin may decrease the risk of endometrial cancer to less than that of untreated women. Alcohol consumption may increase the risk of endometrial cancer by interfering with estrogen metabolism, but this is still a matter of debate. Some endometrial cancer is unexplained by any currently known risk factors.

**DIAGNOSTIC TESTS.** Diagnosis is generally done by endometrial biopsy, but MRI may be used to evaluate invasiveness and involvement of lymph nodes.

**THERAPEUTIC MEASURES.** Depending on the stage of endometrial cancer and metastasis, treatment with hysterectomy, radiation, or chemotherapy may be used.

**Ovarian Cancer**

**PATHOPHYSIOLOGY, ETIOLOGIES, AND SIGNS AND SYMPTOMS.** Ovarian cancer is an especially insidious killer because cellular changes in the ovaries often are asymptomatic until the cancer is advanced. Little is known about what prompts these cells to undergo malignant changes. Risk factors are not definitely identified, but some proposed factors include low fertility and number of children, late menopause, a family history of reproductive or colon cancers, and a diet rich in animal fats. Use of hormonal contraception may help prevent ovarian cancer because it results in less ovulation during a woman’s lifetime.

**DIAGNOSTIC TESTS.** Identification of abnormal growths on the ovaries may begin with bimanual examination, so it is important for women, especially in the older age groups, to continue to have regular pelvic examinations even if they are not sexually active and even if they have had a hysterectomy. Various blood tests measuring tumor marker substances, ultrasonography, CT scanning, and MRI may also be used to assist in diagnosis.

**THERAPEUTIC MEASURES.** Treatment may involve surgical removal of the ovaries by laparoscopy or laparotomy. Sometimes the ovaries are removed to prevent the disease in women who have a high familial risk. Radiation and combination chemotherapy may also be used.

**Nursing Care and Education of Patients With Malignant Disorders**

Radiation therapy for cancers of the reproductive system may involve the placement of radioactive implants into the
patient’s body for 24 to 72 hours. Prevent inappropriate radiation of the patient’s other body parts by such actions as maintaining patency of a urinary catheter to avoid unnecessary exposure of the bladder. Follow institutional guidelines for radiation precautions. A foul-smelling vaginal discharge is expected after radiation by implant because of tissue destruction caused by the radiation; document the amount and character of the discharge. Chemotherapy treatments often cause severe nausea, as well as anorexia and sores of the mouth, vagina, and anus. See Chapter 11 for care of patients receiving radiation or chemotherapy.

See Table 42.9 for a summary of tumors of the reproductive system.

### GYNECOLOGICAL SURGERY

#### Endoscopic Surgeries

Many of the surgeries performed on the reproductive system can be done using an endoscope. The endoscopes used contain

CT = computed tomography; MRI = magnetic resonance imaging.

tiny tools for performing surgery, removal of small areas of diseased tissue and samples, suction, and cauterization of bleeding vessels. Because endoscopic surgeries require tiny incisions (usually less than 1 inch long), there is less tissue disruption and little bleeding compared with traditional surgical techniques. Smaller incisions also present less risk of infection than traditional methods, and recuperation is usually faster with fewer complications.

The danger to the patient is generally low for endoscopic surgeries; however, not all surgical situations can be satisfactorily handled in this way. The size of the cannula restricts the size of tissues that can be removed, unless they can be divided into smaller sections and then pulled out through the cannula. If affected areas are widespread, the endoscope may not be able to reach all sites. Traditional surgery still have may to be done when endoscopic surgery has been ineffective, and this can be frustrating to patients. However, information gained through the previous endoscopic surgery may decrease the time required for a traditional surgery.

Laparoscopies are the most common type of endoscopic surgical procedure used for women’s reproductive system surgeries. This method can be used for access to the abdominal cavity and the anterior portions of the reproductive organs. Tubal ligations, tubal repairs, removal of ectopic pregnancy implantations, removal of small tumors, removal of endometriotic tissue, and aspiration of fluid-filled cysts can all be done by this method.

The newest method of surgery uses computers and robots and is minimally invasive (see Chapter 12). This method allows the surgeon to make a small number of 1- to 2-cm incisions to gain access and three-dimensional visualization into the pelvic cavity. Gynecologically, this method can be used for hysterectomy and myomectomy. The benefits of this method versus other surgical methods are a shorter hospital stay and less pain and scarring for the patient. There is also less risk of infection, less blood loss, fewer transfusions, faster recoveries, and quicker return to normal activities.

Culdoscopies may be done to access the area at the back of the uterus. A **culdotomy**, which is an incision into the upper posterior portion of the vagina, is necessary to insert the cannula. A **culdocentesis**, which is the removal of fluid from the cul-de-sac of Douglas, may be done during a culdoscopy. Aftercare is much the same as for a laparoscopy. The patient should be informed that a small amount of vaginal spotting may be expected from the incision but that heavy, purulent, or foul-smelling discharge should be reported because it could indicate infection.

Colposcopies typically are used to screen, diagnose, or treat problems of the cervix. The binocular microscope attached to the scope cannula, which is introduced into the vagina, allows the HCP to examine dysplastic cells while they
are still in their normal place and to treat cervical dysplasia as previously described.

Hysteroscopy may be used to treat problems within the uterus. Removal of polyps and other growths, modification of congenital malformations such as septa (walls of tissue where there should be none), and laser ablation of endometrial tissue may all be done during hysteroscopy. The endoscope may be inserted further into the fallopian tubes to perform a salpingoscopy, allowing surgical or laser opening of blocked tubes.

**Nursing Care and Patient Education**

Postoperative care involves careful assessment for signs of possible excessive internal bleeding, including assessment of vital signs, skin color and temperature, and pain. Women may experience pain because of carbon dioxide insufflation, which makes the internal organs easier to visualize and manipulate. Measures to reduce the related discomfort while the carbon dioxide is absorbed include instructing the patient to lie flat for a few hours, massaging the back and shoulders, and administering pain medication. Discharge teaching includes instruction about signs of complications to report, medications, and when and where to go for suture removal.

**Hysterectomy**

Removal of the uterus (hysterectomy) may be done for a variety of reasons, including abnormally heavy or painful menstruation, large fibroid or other benign tumors, severe uterine prolapse, and cancer of the uterus. It should not be done merely as a sterilization procedure because the risks involved in hysterectomy are much greater than the risks associated with tubal ligation. The surgery can be done through an abdominal incision (transabdominal hysterectomy, TAH), vaginally, laparoscopically, or robotically. The vagina is left intact and the proximal end (which had been attached to the uterus) is sutured, forming a blind pouch. Although less vaginal lubrication is present after hysterectomy, nerve routes are maintained, and satisfactory sexual intercourse is expected to continue.

There are three types of hysterectomy. Total hysterectomy is the removal of the uterus and cervix; supracervical hysterectomy (also known as partial or subtotal) removes just the upper part of the uterus while the cervix is left in place; and radical hysterectomy, which is the removal of the whole uterus, is performed to remove both sides of the cervix and the upper part of the vagina, done when cancer is present.

Sometimes the choice is made to remove the fallopian tubes and ovaries, which is known as a bilateral salpingectomy and oophorectomy (BSO). If the ovaries are removed, the woman undergoes immediate menopause and may suffer from symptoms associated with menopause, including the increased risks of cardiovascular disease and osteoporosis. If removal of the ovaries is done because of the presence of estrogen-dependent cancer, then estrogen replacement is not usually feasible. Extra care, comfort, and explanation from nurses is needed.

See the "Nursing Care Plan for the Patient Undergoing Hysterectomy." In addition to the nursing diagnoses covered, also assess for anxiety related to surgery, body image disturbance, and for ineffective coping. See Chapters 10 and 12, respectively, for additional interventions for pain and postoperative patients.

---

**NURSING CARE PLAN for the Patient Undergoing Hysterectomy**

**Nursing Diagnosis:** Risk for Ineffective Tissue Perfusion related to surgical incision and removal of the uterus (and possibly the ovaries)

**Expected Outcome:** The patient’s incision(s) will heal by primary intention without excessive bleeding.

**Evaluation of Outcome:** Is dressing dry and intact and/or does perineal pad show less than 3-cm stain every hour? Are edges of the incision well approximated, with scant bleeding/serous drainage, and mild edema/erythema (if applicable)?

**Intervention** Monitor vital signs and oxygen saturation according to hospital policy and as necessary. Rationale Vital signs and oxygen saturation reflect tissue perfusion status. Evaluation Are vital signs stable and within normal range?

**Intervention** Assess for bleeding or other discharge on perineal pad and on abdominal dressing (if applicable). Rationale Excessive bleeding may compromise tissue perfusion and slow healing. Evaluation Is pad or dressing dry? Rationale Vaginal discharge gives clues to healing of incision at the proximal end of the vagina. Evaluation Is discharge foul smelling?

Continued
### NURSING CARE PLAN for the Patient Undergoing Hysterectomy—cont’d

**Intervention** Assess wound healing (if applicable) twice a day and as needed and report any evidence of infection or inadequate healing promptly.  
**Rationale** Early treatment of inadequate wound healing decreases postoperative complications.  
**Evaluation** Is incision area swollen, reddened, or draining purulent material?  

**Intervention** Teach patient to report changes in incision site or excessive bleeding.  
**Rationale** Patients are discharged quickly and should know what to monitor at home.  
**Evaluation** Does patient verbalize understanding of instruction?  

**Nursing Diagnosis:** Risk for Urinary Retention related to manipulation of the bladder and ureters during surgery, anticholinergic drugs, fluid intake changes, and fear of pain  
**Expected Outcome:** The patient will void 30 mL/hr or more without difficulty.  
**Evaluation of Outcome:** Is patient able to void and effectively empty bladder when voiding? Is patient voiding at least 30 mL/hr?  

**Intervention** Assess urinary output after surgery. Report to RN or HCP if less than 30 mL/hr or unable to void.  
**Rationale** Inadequate urinary output can be an evidence of dehydration, low glomerular perfusion, kidney dysfunction, damage to ureter, or urinary retention.  
**Evaluation** Is output greater than 30 mL/hour? Is patient able to void without discomfort?  

**Intervention** Assess bladder fullness using Doppler monitoring or scratch test (listening with a stethoscope, lightly scratch abdomen as you move downward from xiphoid until you hear change in sound indicating top of the bladder).  
**Rationale** Urine retention can cause infection and damage to kidneys, ureters, and bladder. The scratch test and Doppler monitoring cause less discomfort and pressure than palpation of the abdominal incision area.  
**Evaluation** Does patient feel she is emptying fully when voiding? Does Doppler or scratch test indicate residual urine after voiding?  

**Intervention** Medicate for pain on a fixed schedule for operative day and first postoperative day (unless patient declines).  
**Rationale** Maintenance of a consistent blood level of medication in the immediate postoperative period provides relief of pain and promotes voiding without fear of discomfort.  
**Evaluation** Does patient state that she is comfortable?  

**Nursing Diagnosis:** Risk for Constipation related to manipulation of the bowel during surgery, use of opioid analgesics and anticholinergic drugs, diet changes, less exercise than usual, and fear of pain when passing stool  
**Expected Outcome:** The patient will pass soft, formed stool without excessive gas discomfort by third postoperative day.  
**Evaluation of Outcome:** Are bowel sounds active in all four quadrants? Is patient passing gas without difficulty? Is patient able to have a soft, formed bowel movement within 3 days of surgery?  

**Intervention** Assess for active bowel sounds in all four abdominal quadrants before giving anything orally.  
**Rationale** Manipulation of the bowel during surgery and anesthetics or other medications can interfere with bowel function.  
**Evaluation** Are bowel sounds within normal limits?  

**Intervention** Encourage high fluid intake, and graduate diet toward a high-fiber, regular diet as soon as patient is able to tolerate it (or HCP orders prescribe).  
**Rationale** Adequate fluid and fiber in the diet softens the stool for easy passage.  
**Evaluation** Is patient able to tolerate fluids and high-fiber foods?
**Intervention** Encourage adequate exercise. Rationale Reasonable exercise promotes peristalsis and relieves gas discomfort. Evaluation Has patient dangled at bedside the day of surgery and then walked increasing amounts each following day?

**Intervention** Assess quantity and quality of pain. Control pain with analgesics, especially before administering a suppository or enema. Rationale The presence of pain may inhibit defecation. Evaluation Is pain controlled? Does patient express concern about pain with bowel movement?

**Intervention** Administer stool softeners, laxatives, suppositories, or enemas as ordered (check bowel protocol or standing orders). Rationale Soft stool is easier to pass. Evaluation Has patient passed soft, formed stool by the third day after surgery?

---

**SUGGESTED ANSWERS TO CRITICAL THINKING**

**Julie**

1. Questions to further assess Julie’s symptoms should include the following: How long have you been noticing the lumps? Do you do BSEs? Has there been a change in the characteristics of the lumps? Are the lumps mobile or fixed? Have you noticed any breast skin or nipple changes? Have you noticed any leakage of fluid or blood from your breasts? Are you breastfeeding or have you recently delivered an infant? Have you had a fever? Are the pain and lumps related to your menstrual cycle? Is there anything that makes the symptoms better or worse?

2. You can teach Julie to continue to do BSE because she is the best person to detect changes. Teach her that limiting fat and caffeine in her diet may help reduce symptoms. Reinforce any information or treatments provided by the nurse practitioner.

3. If Julie is doing BSE every month, then she knows her breasts better than anyone. She should be vigilant for changes that do not feel like her usual tissue.

**Lola**

1. Interventions that can help control Lola’s discomfort related to hot flashes include possible HRT therapy, inclusion of phytoestrogens in her diet (with HCP direction), limiting caffeinated foods or beverages, dressing in layers so that some may be removed as needed, and lowering the thermostat as needed.

2. Information that should be shared with Lola concerning HRT includes the risks as well as benefits according to most recent studies. Risks include increased risk of stroke, cardiovascular disease, breast cancer, and thromboembolism. Benefits include symptomatic relief and decreased risk of complications from osteoporosis.

3. Collaborate with the HCP, because even herbal remedies can interact with medications and should be recommended by an HCP.

**Jessica**

1. Some important information from Jessica would include her true age (laws vary concerning birth control for minors), her intentions, her family situation, whether she is already sexually active, and what information she wants.

2. She needs to know that being sexually active involves more risks than just pregnancy. Discussion of STIs is vital. Early sexual activity may also be associated with abuse and psychological suffering. The choices of birth control should be explained, including the risks, effectiveness, disadvantages, and advantages of each method. Follow clinic protocol to determine your role in teaching the patient.

3. Potential scenarios can be presented for her “responsible” consideration, such as the following: What would she do if contraceptive failure resulted in a pregnancy? How would she feel if she contracted an incurable or permanently damaging STI that she might pass on to someone else? How would she react to a breakup with her partner after she has engaged in sexual intercourse? Ask about her goals and plans in life. Counseling that evidences concern for the individual at this stage may do a lot to postpone sexual activity until the patient is more mature. It is important for her to realize that choosing to delay sexual activity at this time may be the most responsible and health-promoting life decision she can make.
REVIEW QUESTIONS

1. A patient who is breastfeeding her baby says, “My doctor said I have mastalgia. What does that mean?” Which response by the nurse is best?
   1. “That means you may have an infection in your breasts.”
   2. “Mastalgia is just the normal discomfort that is associated with breastfeeding.”
   3. “The word mastalgia just means breast pain; it can occur with monthly cycles of hormone levels.”
   4. “Mastalgia is the medical term for fibrocystic breast disease. It is important to have it treated promptly.”

2. Which response by the nurse is most appropriate when a 60-year-old woman who has been menopausal for several years relates that she has begun having vaginal bleeding again?
   1. “Don’t be concerned—it is perfectly normal.”
   2. “Try taking some ibuprofen. That may reduce the bleeding.”
   3. “You should see your health care provider to have that checked as soon as possible.”
   4. “Give it time—bleeding after menopause usually goes away within a month.”

3. During an endometrial biopsy, for which of the following signs and symptoms of vasovagal response should the nurse observe?
   1. Pain in the chest and abdomen
   2. Cramping and diaphoresis
   3. High blood pressure and tachycardia
   4. Bradycardia and falling blood pressure

4. Which of the following medications can be used to treat vasovagal response during gynecological procedures? Select all that apply.
   1. atropine
   2. morphine
   3. epinephrine
   4. metoprolol
   5. naproxen

5. The nurse is discharging a patient with endometriosis from an office visit. The patient says her medication helps but does not relieve all her discomfort. What other measures can the nurse recommend?
   1. “Check with the health food store. There are several herbal remedies that can be very effective.”
   2. “Try using the relaxation exercises you learned in your childbirth classes. A warm compress to your abdomen might also help.”
   3. “You can double up on your pain medication on occasion, but you shouldn’t do it on a regular basis.”
   4. “If the medications aren’t effective, then it is time to talk to the physician about a hysterectomy.”

6. The nurse enters the room of a patient who is 1-day postoperative left-sided mastectomy and notes a phlebotomist taking blood from her left antecubital space. What should the nurse do first?
   1. Nothing; the nurse is not the phlebotomist’s supervisor.
   2. Nothing; blood pressures should be avoided in the affected arm, but blood draws are safe.
   3. Stop the phlebotomist and ask that the blood be drawn from the right arm.
   4. Notify the health care provider.

7. Following a total hysterectomy with bilateral oophorectomy (BSO), what should the nurse teach the patient to expect?
   1. Heavy bleeding for a week
   2. Symptoms of menopause
   3. Painful intercourse for approximately 6 months
   4. Monthly cramping but no menstrual flow

8. A patient who has just returned from a transabdominal hysterectomy is at risk for impaired urinary elimination. At least how many milliliters should be in her catheter bag 8 hours postoperatively? Fill in the blank. Answer: __________ mL

9. Which of the following is the least effective form of contraception?
   1. Douching
   2. Condom with spermicide
   3. Diaphragm with spermicide
   4. Oral contraceptive medication

Answers can be found in Appendix C.

LEARNING OUTCOMES

1. Explain the pathophysiology associated with each male genitourinary and reproductive disorder discussed in this chapter.
2. Describe the etiologies, signs and symptoms, and treatments of prostate disorders.
3. Plan nursing care for men with genitourinary and reproductive disorders.
4. Describe disorders of the testicles and penis and how they affect sexual function.
5. List selected physical and emotional causes of erectile dysfunction.
6. Discuss the nurse’s role in helping men cope with loss of sexual function.
7. Identify disorders of the male reproductive system that interfere with fertility.
8. List treatment options available for male infertility.
Problems affecting the male genitals and urinary system typically are difficult areas for both the patient and the nurse to deal with because of the sexual nature of the male anatomy. Nurses need to realize that sexuality is a natural part of each of us as human beings and should not be a voided when we provide care to patients. Often the nurse is an ideal person to provide important sexual health care teaching. If the patient is approached in a confident, confidential manner, discussions about sexual health can be positive learning experiences for both the patient and the nurse.

Some good general health guidelines for men can be found at the Agency for Healthcare Research and Quality’s Put Prevention into Practice website at www.ahrq.gov/ppip/healthymen.htm.

PROSTATE DISORDERS

The prostate gland sits at the base of the bladder and wraps around the upper part of the male urethra like a doughnut. The primary purpose of the prostate is to provide alkaline secretions to semen and to aid in ejaculation. The prostate does not contain any hormones; however, many men fear that prostate problems and treatment will cause problems with their erections or their sexual activities.

Prostatitis

Pathophysiology

Prostatitis, or inflammation of the prostate gland, can occur any time after puberty. The problem can be chronic or a single, acute episode. The inflammation causes the prostate gland to swell, resulting in pain, especially when standing. It can eventually lead to difficulty in passing urine as a result of an inward squeezing on the urethra and restricted urine flow.

Etiology

According to the National Institutes of Health, there are four basic types of prostatitis: (1) acute bacterial, (2) chronic bacterial, (3) chronic prostatitis/chronic pelvic pain syndrome, and (4) asymptomatic inflammatory prostatitis (National Kidney and Urologic Diseases Information Clearinghouse, 2012). Bacterial prostatitis is most common in older men. It results in edema and inflammation of all or part of the prostate gland.

Any bacteria that can cause a urinary tract infection can also cause infectious prostatitis. Common bacteria are organisms such as Escherichia coli and Staphylococcus aureus. Sexually transmitted infections (STIs) can also cause prostatitis. The prostate gland may become infected in the following ways:
- Bacteria ascending the urethra
- Infected urine refluxing from the bladder into the prostatic ducts
- Bacteria in the blood or lymph supply to the gland
- Surgical instrumentation or other forms of urethral trauma.

Prevention

Ways to avert prostatitis are regular and complete emptying of the bladder to prevent urinary tract infection (UTI), avoiding excess alcohol (more than 2 to 3 oz per day—alcohol is a bladder irritant), and a voiding high-risk sexual practices, such as multiple partners.

Signs and Symptoms

The most common symptoms are those that occur with any UTI: urgency, frequency, hesitancy, dribbling, and dysuria. Because of the location and function of the prostate gland, the patient may report low-back, perineal, and postejaculation pain. He may also have a fever and chills.

Complications

One complication of acute bacterial prostatitis is urinary retention. If the prostate is extremely swollen, the bladder cannot be completely emptied. Another complication may be a temporary problem with erections. Ascending infections, prostatic abscess, epididymitis, and prostatic calculi (stones) are some of the more serious and rare complications of prostatitis.

Diagnostic Tests

Initial diagnosis is based on symptoms. The first test performed is a careful, gentle, digital rectal examination of the prostate. The prostate gland is examined by the health care provider (HCP) by insertion of a gloved finger into the rectum. The examiner may find a warm, irregular, swollen, and painful prostate gland. A urine culture generally is positive for bacteria. The examiner may also gently massage the prostate gland and order an expressed prostate secretion test that reveals bacteria and a large number of white blood cells. Cystoscopy also may be done.

Therapeutic Measures

Acute bacterial prostatitis is treated with antibiotic therapy. Additional treatments may include anti-inflammatory agents, stool softeners, warm sitz baths, prostatic massage, and dietary changes such as decreasing spicy foods and alcohol. Alpha-adrenergic blockers such as alfuzosin (Uroxatral) can help relax the bladder neck and reduce the pain on urination (Table 43.1). In some cases, prostate surgery is needed to remove the obstruction.

BE SAFE!

BE VIGILANT! Patients with prostate disorders should avoid alpha-adrenergic agonist and anticholinergic medications, which can cause urine retention.

Nursing Process for the Patient With Prostatitis

DATA COLLECTION. Begin the assessment by asking the patient to describe signs and symptoms that indicate evidence of a UTI, such as sudden fever, chills, and reports of urgency, frequency, hesitancy, dysuria, and nocturia. The patient may also have pain in the lower back, the perineum, or after ejaculating. Ask the patient if he has ever had a UTI or prostate infection in the past. Care must be taken to assess urinary retention resulting from obstruction. Obtain a urine culture and assist with collection of the expressed prostate secretion (EPS) specimen, if requested, as part of the patient assessment.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.

Urinary Retention related to obstruction as evidenced by residual urine in bladder after voiding

EXPECTED OUTCOME: The patient will be able to void effectively as evidenced by residual urine of less than 25% of bladder capacity.

- Evaluate patient’s medications for urinary retention as a side effect. Many medications, especially those with anticholinergic effects, can cause urinary retention.
- If suspicion of urine retention is present, determine residual urine volume by catheterizing patient (according to HCP order) or obtaining a bladder ultrasound immediately after voiding. Incomplete emptying of the bladder may lead to increased discomfort or ascending infection.
- Have the patient complete a bladder log including patterns of elimination and related symptoms, as well as volume/type of fluid consumed for 3 to 7 days. This will provide for an objective verification of intake and output volumes and aid in determination of urinary retention.
- Educate patient about avoidance of risk factors for urine retention (e.g., alpha-adrenergic agonists, anticholinergic agents, overfilling of the bladder). These are modifiable variables that may limit retention of urine.
- Report urine retention to registered nurse (RN) or HCP. Catheterization may be needed to empty bladder and prevent complications.

Deficient Knowledge About Cause, Treatment, and Prevention of Prostatitis

EXPECTED OUTCOME: The patient will verbalize understanding of disorder and demonstrate appropriate self-care.

- Determine patient’s current knowledge and understanding about cause and treatment of prostatitis. This will allow for additional and/or correct information to be provided about the disorder for appropriate understanding.
- Provide patient with additional and/or correct information about the cause and treatment of prostatitis. This will allow the patient to have a full understanding of the etiology and care related to the disorder and increase likelihood of patient adherence to treatment.
- Teach avoidance of risk factors such as urinary catheterization, poor hygiene, risky sexual practices, and excessive intake of bladder irritants such as alcohol, caffeine, or citrus juices. Avoiding risk factors is important to resolving or preventing prostatitis.
- Encourage the patient to wash his hands and sitz bath equipment before and after each treatment to prevent infection.
- Encourage the patient to empty his bladder every 2 to 3 hours even if he does not feel the urge to urinate. An overstretched bladder increases risk of infection.
- Encourage fluids such as water and cranberry juice up to 2500 to 3000 mL/day unless contraindicated by heart failure or other chronic illness. Fluids help flush the bladder and prevent infection.
- Include patient’s partner in care. Some treatment options may also include treatment of the partner (e.g., STIs such as gonorrhea, chlamydiosis, or trichomoniasis; see Chapter 44).
- Explain use of antibiotics as directed, and advise patient to take complete course of medication to best treat infection and prevent development of antibiotic-resistant bacteria.

Acute Pain related to swelling and irritation of the prostate gland as evidenced by pain rating

EXPECTED OUTCOME: The patient’s pain will be controlled as evidenced by patient statement that comfort is at an acceptable level.

- Use a culturally appropriate pain scale to help patient identify comfort level. This will aid in understanding comfort level as defined by the patient and aid in guiding appropriate interventions.
- Encourage appropriate use of anti-inflammatory medication as ordered. This will decrease inflammation and promote comfort.
- Encourage use of comfort measures such as warm sitz baths, sitting on a pillow, or prostatic massage, as needed, to decrease swelling and promote comfort.
- Teach patient to avoid spicy and acidic foods, alcohol, and caffeine. These can exacerbate symptoms.
- Consult HCP about need for stool softeners. Firm stool will further irritate the prostate during defecation and increase discomfort.

Anxiety related to sexual concerns as evidenced by patient statement

EXPECTED OUTCOME: The patient will identify presence of anxiety and verbalize concerns about sexuality.

- Identify source of concern related to sexual activity and meaning assigned to disorder as described by patient. This will help in guiding appropriate interventions.
- Explore coping skills previously used by patient to relieve anxiety; reinforce these skills and explore other outlets for stress management. Coping mechanisms that have been helpful in the past can aid patient in dealing with current stressors that result in anxiety.
- Encourage patient to discuss possible complications and questions about sexual practices with his HCP. In some cases, sexual intercourse is encouraged as a means of relieving prostatic congestion; in other situations, it may be contraindicated.
Benign Prostatic Hyperplasia

Enlargement of the prostate gland is a normal process in older men. It begins around age 50 and exists in 75% of men older than age 70. Benign prostatic hyperplasia (BPH) is a nonmalignant growth of the prostate that gradually causes urinary obstruction. According to current studies, BPH does not increase a man’s risk of developing cancer of the prostate.

Pathophysiology

A slow increase in the number of cells in the prostate gland is generally the result of aging and the male hormone dihydrotestosterone. As the size of the prostate gland increases, it begins to compress or squeeze the urethra. Narrowing of the urethra means that the bladder must work harder to expel the urine. More effort and a longer time is needed to empty the bladder. Eventually the narrowing causes obstruction and can lead to urine retention or eventually distention of the kidney with urine (hydronephrosis).

The location of the enlargement, rather than the size, determines symptoms. A small growth in the prostate gland closest to the urethra can cause more problems with urination than a growth the size of an orange in the outer portion of the gland.

Etiology

There is no known cause of BPH other than normal aging. Some men think they may have caused the problem by certain sexual practices; however, there is no scientific proof of that at this time. Some factors that are being investigated in research studies are high-fat diet and ethnic background.

Prevention

Because there is no known cause, there is no proven method to prevent enlargement of the prostate gland. New treatments are aimed at slowing down the enlargement process. One such treatment that is being researched is the herbal supplement saw palmetto.

Signs and Symptoms

Symptoms of BPH are usually identified in two ways: problems related to obstruction or problems related to irritation. Symptoms related to obstruction include a decrease in the size or force of the urinary stream, difficulty in starting a stream, dribbling after urination is complete, urinary retention, and a feeling that the bladder is not empty. The patient may also experience overflow incontinence or an interrupted stream where the urine stops midstream and then starts again.

Symptoms related to irritation include nocturia, dysuria, and urgency. HCPs may use a standardized symptom score index tool with patients to assess symptoms and determine treatment options.

Complications

When BPH is untreated and obstruction is prolonged, serious complications can occur. Urine that sits in the bladder for too long can back up into the kidneys, causing hydronephrosis, renal insufficiency, or urosepsis; it can also damage the bladder walls, leading to bladder dysfunction, recurrent UTIs, or calculi (stones). Acute urine retention with total inability to urinate can occur; this is a medical emergency that requires catheterization.

Diagnostic Tests

The first test is usually digital rectal examination of the prostate to assess for enlargement and whether the gland is hard, lumpy, or “boggy.” Additional tests include urinalysis, blood urea nitrogen (BUN), serum creatinine, and prostate-specific antigen (PSA). Secondary tests include urodynamic flow studies, which may show a decreased urine flow rate. Transrectal ultrasound of the prostate and cystoscopy can reflect structural abnormalities.

Therapeutic Measures

If the patient has no symptoms or mild symptoms, the most current medical approach is “watchful waiting.” The HCP watches for any increase in symptoms that suggest the urethra is becoming obstructed. Treatment of symptoms may include use of a catheter (indwelling or intermittent), encouraging oral fluids, and antibiotics for UTI.

Conservative medical treatment includes the use of medication to either relax the smooth muscles of the prostate and bladder neck or block the male hormone to prevent or shrink tissue growth. Alpha-adrenergic antagonists, such as tamsulosin (Flomax), are medications that relax the smooth muscles. These medications are also used to treat high blood pressure; therefore, patients need to work closely with their HCPs to avoid overdose or the negative side effects of postural hypotension (see Table 43.1).

The most commonly used medications to block the action of the male hormone in the prostate gland are finasteride (Proscar) and dutasteride (Avodart). These medications must be taken on a long-term, continuous basis to achieve results. Conservative measures are used initially unless the patient is experiencing recurring infections, repeated gross hematuria, bladder or kidney damage, evidence of cancer, or unsatisfactory lifestyle changes.

Nonsurgical invasive treatments, some of which are experimental, are available in some areas of the country in addition to surgical options. These include transurethral microwave therapy, which involves heat applied directly to the gland to inhibit growth; transurethral needle ablation; and high-intensity focused ultrasound, which uses radio or sound waves to destroy parts of the gland. Prostatic stents may be used to open the passageway for urine to flow more freely.

* WORD * BUILDING *

urosepsis: uro—urine + sepsis—systemic infection
urodynamic: uro—urine + dynamic—force
Surgical Treatment

Because so many other treatments are available now, surgery is not needed as often. When symptoms are severe enough to require surgery, several types are available, as described next.

**TRANSURETHRAL RESECTION OF THE PROSTATE.** Called TURP, this is the surgical treatment used most often to relieve obstruction caused by an enlarged prostate (Fig. 43.1). Several other transurethral options also exist. Transurethral incision of the prostate (TUIP) uses surgical incisions into the gland to relieve obstruction. Transurethral ultrasound-guided laser-induced prostatectomy uses a laser to relieve obstruction.

For TURP, the patient is anesthetized, and the surgery is performed using an instrument called a resectoscope. The resectoscope is inserted into the urethra, and the prostate gland is “chipped” away a piece at a time. Special surgical instruments are used to “vaporize” or “micro wave” the pieces and cut down on the amount of bleeding during surgery. During routine TURP, the “chips” are flushed out using an irrigating solution and are sent to the laboratory to be analyzed for possible evidence of cancer. The prostate gland is not completely removed but peeled away like the rind of an orange. The prostatic tissue that remains eventually grows back and can cause obstruction again at a later time. Patients need to be reminded to continue having yearly prostate examinations.

As the tissue is removed during TURP, bleeding occurs. A Foley catheter is left in place with 30 to 60 mL of sterile water inflating the balloon. The balloon is overfilled and may be secured tightly to the leg or abdomen to tamponade (compress) the prostate area and stop the bleeding. Irrigation solution generally flows continuously (Fig. 43.2); manual irrigation may be done for the first 24 hours to help remove clots and chips and maintain catheter patency. The Foley catheter is removed after the danger of hemorrhage has passed.

**You may need to save “serial urines” to monitor for bleeding. To do this, each time the patient urinates or the catheter bag is emptied, save a sample of urine in a transparent cup. Place it in a safe place, such as on a shelf in the bathroom. With each subsequent urination, place the new cup to the right of the previous cup. When five or six cups are lined up, you can start over at the left side, replacing the oldest cup with the newest one. This allows the nurse or HCP to examine the urine for progressively less blood with each void.**

Complications associated with prostate surgery depend on the type and extent of the procedure performed. The main medical complications include clot formation, bladder spasms, and infection. Less common complications are urinary incontinence, hemorrhage, and erectile dysfunction (see the “Nursing Care Plan for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia”).

**Retrograde** ejaculation is a common result of prostate surgery. When any of the prostate gland is removed, there is a decrease in the amount of semen produced and a part of the ejaculatory ducts may be removed. This results in less semen being pushed outside the body, and instead it “falls back” into the bladder. This causes no harm; the semen is simply passed during the next urination.

<tr>
<td>Evaluation of Outcome:</td>
<td>Is urine clearing? Is bleeding reported promptly?</td>
</tr>
</tbody>
</table>

**Intervention** Closely monitor urinary output in terms of amount, color, and presence of clots at least every hour for the first 24 to 48 hr postoperatively. Monitor serial urines. **Rationale** Careful monitoring and reporting of changes can help prevent major complications. **Evaluation** Is urine becoming progressively less bloody and more clear with each void?

**Intervention** Explain to patient that some bloody urine is normal after a TURP, as long as it does not suddenly get much worse. Also explain that a little blood mixed with irrigating fluid in a Foley bag may look worse than it actually is. **Rationale** Seeing the catheter bag filled with bloody drainage may be upsetting to a patient or his family. **Evaluation** Is urine becoming progressively less bloody and more clear with each void?

**Intervention** Encourage patient to drink up to 2500 mL/day (unless contraindicated by other medical conditions) of water, noncitrus juices, and other noncaffeinated, nonalcoholic beverages. **Rationale** Increasing urine flow can help flush blood from bladder. **Evaluation** Is patient drinking adequate amounts?

**Intervention** Teach patient to avoid constipation (suggest stool softener, fluids, prune juice) and heavy lifting. **Rationale** These can increase pressure in the abdomen and increase risk of bleeding. **Evaluation** Does patient verbalize understanding of instructions?

**Intervention** Advise patient to lie down if urine becomes bright red or has large clots. **Rationale** Activity can increase bleeding. **Evaluation** Does patient reduce activity if bleeding increases?

**Intervention** Teach patient to avoid aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) until risk of bleeding is over. **Rationale** Aspirin and NSAIDs inhibit platelet function and increase risk of bleeding. **Evaluation** Does patient verbalize understanding?

</thead>
<tbody>
<tr>
<td>Expected Outcome:</td>
<td>The patient’s pain will be controlled as evidenced by patient statement of lower pain rating.</td>
</tr>
<tr>
<td>Evaluation of Outcome:</td>
<td>Does patient state that pain is decreased to acceptable level?</td>
</tr>
</tbody>
</table>

**Intervention** Monitor pain on an appropriate scale every 2 to 4 hr for first 48 hr and within 30 minutes after any intervention. **Rationale** A pain scale is the most accurate measure of pain. **Evaluation** Does patient verbalize pain as increasing or decreasing on the scale?

**Intervention** Monitor for signs of pain related to bladder spasms, obstruction, or surgical process, such as facial grimaces, irrigation solution that does not flow into bladder, urinating around catheter, multiple clots. **Rationale** Relief of mechanical cause of pain promotes comfort, rest, and healing. **Evaluation** Is patient free from signs of pain related to bladder spasms, obstruction, or surgical process?

**Intervention** Administer prescribed medication (analgesics, antispasmodics such as B&O suppository) and monitor response. **Rationale** B&O suppositories relieve bladder spasms. **Evaluation** Does patient state relief when medications are given?
**NURSING CARE PLAN for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia—cont’d**

**Intervention** Irrigate catheter as ordered. **Rationale** Irrigation promotes removal of clots to reduce spasms and pain. **Evaluation** Does irrigating solution flow in and out easily?

**Intervention** Educate patient regarding nonpharmacological methods to control pain such as relaxation and deep-breathing techniques. **Rationale** Relaxation calms spasms and relieves pain. Nonpharmacological measures should be used with, not in place of, medication. **Evaluation** Are clots being removed? Is patient able to relax?

**Nursing Diagnosis:** Urge Urinary Incontinence related to poor sphincter control as evidenced by inability to control urination

**Expected Outcome:** The patient will be able to prevent incontinence.

**Evaluation of Outcome:** Is incontinence prevented?

**Intervention** Teach Kegel (pelvic floor) exercises (see Chapter 42)—to be practiced every time patient urinates and throughout the day. **Rationale** Kegel exercises strengthen muscle tone to hold urine after catheter is removed. **Evaluation** Is patient able to start and stop urine stream?

**Intervention** Discuss use of condom catheter or penile pads. **Rationale** These can keep patient dry until incontinence can be controlled. **Evaluation** Does patient indicate an informed choice of incontinence products?

**Intervention** Instruct patient to continue drinking 2000 to 4000 mL of noncaffeinated, nonalcoholic beverages each day. **Rationale** Adequate nonirritating fluid intake is important for healing and preventing UTI. **Evaluation** Does patient drink adequate fluids even though he dribbles?

**Intervention** Encourage patient to discuss long-term (longer than 6 months) incontinence problems with HCP. **Rationale** Patient may need to learn self-catheterization or try medication. **Evaluation** Does patient verbalize understanding of what to do if incontinence continues?

**Intervention** Refer patient to national incontinence support group if indicated. **Rationale** Support groups can provide information and emotional support. **Evaluation** Does patient show interest in a support group?

**Nursing Diagnosis:** Deficient Knowledge related to lack of experience with postoperative restrictions and care

**Expected Outcomes:** The patient will avoid activities that increase intra-abdominal pressure resulting in excessive bleeding. The patient will verbalize understanding of how to prevent postoperative infection.

**Evaluation of Outcomes:** Does patient verbalize understanding of how to prevent bleeding? Is infection prevented?

**Intervention** Teach patient to avoid lifting heavy objects (more than 10 lbs), stair climbing, driving, strenuous exercise, constipation, straining during bowel movements, and sexual activities until approved by HCP (about 6 weeks). **Rationale** Heavy lifting or straining can disrupt the healing process and result in tissue damage or excess bleeding. **Evaluation** Does patient verbalize understanding of reasons for limitation of heavy lifting and straining?

**Intervention** Instruct patient on proper catheter care if patient will be discharged with catheter. Include the following information: • Keep catheter tubing secured to abdomen or thigh and keep bag below bladder. • Wash catheter/meatus junction with soap and water once daily. • Use clean technique with good hand hygiene to change from leg bag to night drainage bag. • Report signs and symptoms of UTI to HCP immediately. • Encourage oral fluids. **Rationale** UTIs are extremely dangerous and can cause death following genitourinary surgery in an older patient. **Evaluation** Can patient give a return demonstration of proper catheter care? Is patient free from signs and symptoms of infection?
NURSING CARE PLAN for the Postsurgical Patient Having Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia—cont’d

**Intervention** Teach all patients to report bleeding that is not stopped with resting; fever; swelling; or difficulty urinating to HCP promptly. **Rationale** These are signs of complications that may require prompt medical intervention. **Evaluation** Does patient verbalize understanding of signs and symptoms to report?

**Nursing Diagnosis:** Anxiety related to concerns over loss of sexual functioning following prostate surgery as evidenced by patient statement

**Expected Outcomes:** The patient will verbalize normal sexual changes that happen after prostate surgery. The patient will identify available support systems if needed.

**Evaluation of Outcomes:** Is patient able to verbalize understanding of expected body function after prostate surgery? Does the patient access support systems?

**Intervention** Explain to patient that he will probably have retrograde ejaculation into bladder after surgery. It is not harmful and semen will come out when he urinates. **Rationale** Removal of the prostate gland often results in retrograde ejaculation. **Evaluation** Does patient understand what will happen when he ejaculates?

**Intervention** Instruct patient to talk with urologist if erection problems occur. **Rationale** Urologists who specialize in treatment of erectile dysfunction can provide information and treatment. **Evaluation** Is patient aware of local support services?

---

It is important to understand that erection, ejaculation, and orgasm are all separate actions. Erection means the penis becomes hard, ejaculation is the release of semen, and orgasm is felt as pulsations along the urethra. Unless additional problems are present, the patient continues to have erections and orgasmic sensations but decreased or no ejaculation.

**RADICAL PROSTATECTOMY.** When the prostate gland is very large, is causing obstruction, or is cancerous, a radical prostatectomy may be performed to remove the entire prostate gland. **Open Prostatectomy.** Several approaches may be taken during traditional radical surgery (Fig. 43.3). In the suprapubic approach, an incision is made through the lower abdomen into the bladder. The gland is removed, and the urethra is reattached to the bladder. The retropubic approach is similar except there is no incision into the bladder. A perineal prostatectomy involves making an incision between the scrotum and anus to remove the gland. This procedure is rarely done because of the increased risk of contamination of the incision (close to the rectum), and risk of urinary incontinence, erectile dysfunction, or injury to the rectum.

An open prostatectomy means a longer hospital stay compared with other BPH surgeries. The presence of a suprapubic catheter and care for an abdominal incision increase the length of stay and risk for complications. Follow-up home care for wound and catheter care is important for these patients.

**Minimally Invasive Prostatectomy.** Newer techniques use laparoscopy and tiny robot arms to perform radical prostatectomy through five small “porthole” incisions in the abdomen. The surgeon makes all the decisions about the surgery while guiding the robotic arms. The robotic arms allow more precision and maneuverability, especially in small areas. Because robotic surgery is so much less invasive, patients experience better results with less postoperative bleeding and incontinence and shorter hospital stays.

**Nursing Process for the Patient With BPH Who Undergoes a TURP Procedure**

**DATA COLLECTION.** Begin by asking the patient if he has ever had treatment or surgery for prostate trouble. Assess amount and type of fluid intake per day and whether the patient has noticed any of the symptoms of BPH. Monitor output, and, if he is not catheterized, ensure that urine retention is being managed appropriately.

**NURSING DIAGNOSES, PLANNING, AND INTERVENTIONS.** For nursing care of the patient following TURP, see the “Nursing Care Plan for the Postsurgical Patient Having...”

---

**Note.** B&O = belladonna and opium; NSAIDs = nonsteroidal anti-inflammatory drugs; TURP = transurethral resection of the prostate; UTI = urinary tract infection.
Transurethral Resection of the Prostate for Benign Prostatic Hyperplasia.” In addition, each patient experiences individual responses and needs. Care plans must be individualized, keeping in mind that the majority of these patients are older and have secondary medical problems such as cardiovascular disease.

**EVALUATION.** A patient should be discharged home with a minimum of bladder discomfort, light pink to clear urine, no evidence of UTI, and knowledge related to self-care at home. Home care nursing may be required if the patient lives alone or does not have the capacity to provide for meals, toileting, or transportation for the follow-up visit. Table 43.2 provides a summary of BPH.

**CRITICAL THINKING**

**Mr. Atkinson**

- Mr. Atkinson is a 68-year-old African American farmer with an enlarged prostate gland. He lives on a 75-acre farm with his wife and one son. He is scheduled for a TURP in 6 weeks.

1. Mr. Atkinson is currently taking terazosin (Hytrin), and his HCP wants him to increase his dose from 2 to 5 mg daily until surgery. He has a bottle at home of 2-mg tablets. How should you instruct him to take his medication? What side effect should he be advised to watch for?
2. What special postoperative instructions should he be given because of his occupation?
3. What should you tell him if he asks about how the surgery will affect his “nature” (sexual activities)?
4. What other health team members can you collaborate with and anticipate Mr. Atkinson might need while in the hospital or when he goes home?

*Suggested answers are at the end of the chapter.*

---

**Cancer of the Prostate**

Cancer of the prostate is the most common cancer in American men. Most prostate cancers grow very slowly and often do not cause a major threat to health or life. Many treatment options are available, and the prognosis is often very good.

**Pathophysiology**

Prostate cancer depends on testosterone to grow. The cancer cells are usually slow growing and begin in the posterior (back) or lateral (side) part of the gland. The cancer spreads by one of three routes. If it spreads by local invasion, it will move into the bladder, seminal vesicles, or peritoneum. The cancer may also spread through the lymph system to the pelvic nodes and may travel as far as the supraclavicular nodes. The third route is through the vascular system to bone, lung, and liver. Prostate cancer is staged or graded based on the growth or spread.
Etiology
Age is the primary risk factor. Prostate cancer is found most often in men older than age 65 and is rare in men younger than age 40. Other risk factors are higher levels of testosterone, high-fat diet, and immediate family history.

Prostate cancer rates are highest in African American men and lowest in American Indian and Native Alaskan men (American Cancer Society, 2012). Occupational exposure to cadmium (e.g., welding, electroplating, alkaline battery manufacturing) has been identified as an added risk factor.

Signs and Symptoms
Symptoms are rare in the early stage of prostate cancer. Later stages include symptoms of urinary obstruction, hematuria, and urinary retention. Advanced (metastatic) stage symptoms can include pain in the back or hip from metastasis to the bone, anemia, weakness, weight loss, and overall tiredness.

Complications
Early complications of prostate cancer are related to bladder problems, such as difficulty urinating, and bladder or kidney infection. Erectile dysfunction can occur as a result of the cancer or its treatment (see “Evidence-Based Practice” box).

If the cancer metastasizes, the patient may develop problems such as pain, bone fractures, weight loss, and depression; eventually death can occur if treatment is not successful.

### EVIDENCE-BASED PRACTICE

**Clinical Question**
What interventions are available for men with sexual dysfunction after treatment for prostate cancer?

**Evidence**
Two Cochrane reviews have looked at treatments for erectile dysfunction. The first found that focused group therapy was as effective as local injection or vacuum devices, and that group therapy combined with drug therapy (sildenafil [Viagra]), was more effective than drug therapy alone (Melnik, Soares, & Nasello, 2008). The second found that PDE5 inhibitors (such as sildenafil [Viagra] and tadalafl [Cialis]) are effective following treatment for prostate cancer (Miles et al, 2012).

**Implications for Nursing Practice**
Nurses can play a role in assessing men’s knowledge of interventions for erectile dysfunction related to treatment for prostate cancer. Although specific intervention is beyond the scope of practice of the licensed practical nurse/licensed vocational nurse (LPN/LVN), it is appropriate to advise men that medications, local injections, vacuum devices, and group therapy have all been shown to help, and refer them to their HCPs for further assistance.

**REFERENCES**

Diagnostic Tests

A routine digital rectal examination of the prostate is the first test; often the examiner finds a hard lump or hardened prostate lobe. Blood tests looking for high levels of PSA or PAP may be done. When there is a palpable tumor, the HCP may order a transrectal ultrasound and biopsy to help confirm the diagnosis. Bone scans and other tests may be ordered to determine if the cancer has spread outside the prostate gland.

In the past, the PSA test was used to screen men for prostate cancer, but more recently, the American Cancer Society withdrew this recommendation because routine screening has not been found to save lives. Instead, many slow-growing, noninvasive cancers were discovered and treated. Although aggressive cancers require treatment, many prostate cancers are not aggressive, and the treatment may be worse than the disease. Patients with elevated PSA levels may now have additional testing to determine how aggressive the cancer is, so that appropriate treatment decisions can be made.

Therapeutic Measures

Prostate cancer in the early stages may be treated with testosterone-suppressing medications, such as leuprolide (Lupron) or goserelin (Zoladex), or drugs that block testosterone’s action on the prostate gland, such as bicalutamide (Casodex). Surgery, such as TURP or radical prostatectomy, or a combination of medication and radiation therapy may be done. In later stages, the treatment is usually a radical prostatectomy, radiation therapy, or implantation of radioactive “seeds” into the prostate (brachytherapy). A new vaccine, sipuleucel-T (Provenge) that will slow the growth and aggressiveness of some prostate cancers is currently being tested.

Metastatic prostate cancer treatment involves relief of symptoms or blocking testosterone by bilateral orchiectomy, administration of antiandrogen (flutamide [Eulexin]), or use of agents such as leuprolide and goserelin. Sometimes chemotherapy is used to help relieve symptoms resulting from spread of the cancer.

Unfortunately, any therapy that reduces androgen activity in a man can cause side effects, such as hot flashes, breast tenderness and growth, osteoporosis, and loss of muscle mass. These in turn can cause significant concerns with body image.

Brachytherapy, external-beam radiation therapy, and radical prostatectomy combinations are showing favorable results in the treatment of advanced cancer. Gene therapy and immune-based interventions are also under investigation.

RADICAL PROSTATECTOMY. A radical prostatectomy (described earlier in this chapter) is done for patients with cancer of the prostate or when the gland is too large to resect using a less invasive method.

The patient returns from surgery with a large indwelling catheter in the urethra and may also have a suprapubic catheter. A drain is often placed to remove fluids from the abdominal cavity and allow the wound to heal from the inside outward. Special care must be taken to keep the incision and drain sites clean and dry. Dressings should be changed according to institution policy using sterile technique.

Radical prostatectomy has more complications associated with it than any other treatment option. The major complications are hemorrhage, infection, loss of urinary control, and erectile dysfunction.

Patient Education

All men older than age 40 should be encouraged to have a yearly digital rectal examination of the prostate. Prevention and early detection are the best ways to fight prostate cancer.

PENILE DISORDERS

Problems of the penis, aside from those caused by STIs, are fairly rare but may cause great concern and worry for the patient. Many men have difficulty seeking help for such a personal problem. It is important to be sensitive when assessing or providing care for these patients.

Peyronie’s Disease

Peyronie’s disease gives the penis a crooked or crooked look when it is erect. Fibrous bands or plaques form mainly on the dorsal (top) part of the layer of tissue that surrounds one of the corpora cavernosa of the penis. The plaque may be caused by injury or inflammation of the penile tissue, or it may come and go spontaneously. If the plaque is thick enough, it can cause curvature, painful erection, difficulty in vaginal penetration, and erectile dysfunction. When conservative treatments such as oral vitamin E, colchicine, or potassium aminobenzoate do not work, surgery may be needed to remove the plaque. Another option is injections into the scar tissue to break it down. Patients need to be reassured that the problem is not life threatening and can be treated.

Priapism

Priapism is a painful erection that lasts longer than 4 hours. If not relieved, it can become a medical emergency. The small veins in the corpora cavernosa spasm, so blood cannot drain back out of the penis as it should. When the blood cannot drain, penile tissue does not get oxygen, and permanent tissue damage can result. There may be a complete loss of erection ability after the priapism episode. Prolonged priapism can also prevent the patient from passing urine, which can lead to painful bladder and kidney problems. Some causes of priapism are sickle cell anemia, leukemia, widespread cancer, spinal cord injury or tumors, and use of medications to manage erectile dysfunction (such as sildenafil [Viagra]) or recreational drugs such as crack cocaine. Treatment in the emergency department may include ice packs, sedatives, analgesics, injection of medications directly into the penis to relax the vein spams, needle aspiration, and irrigation of the corpora. Surgery to implant a shunt that reroutes blood flow can also be done.

Word Building

**Orchiectomy**: orchi—testicles + ectomy—excision

**Priapism**: priap—phallos + ism—condition of
**Phimosis and Paraphimosis**

**Phimosis** is the term used to describe a condition in which the foreskin of an uncircumcised male becomes so tight that it is difficult or impossible to pull back away from the head of the penis. It may make it impossible to clean the area underneath. Smegma, a cottage cheese-like secretion made by the glands of the foreskin, becomes trapped under the foreskin and is an excellent place for the growth of bacterial and yeast infections. Antibiotics and warm soaks may be ordered if infection is present. Topical steroid ointment and stretching exercises for the foreskin may be prescribed. A circumcision may be recommended if the problem continues. Phimosis is generally prevented by teaching uncircumcised males to pull the foreskin back carefully, wash with mild soap and water daily, and replace the foreskin to its normal position.

**Paraphimosis** occurs when the uncircumcised foreskin is pulled back, during intercourse or bathing, and not immediately replaced in a forward position. This causes constriction of the dorsal veins, which leads to edema and pain. Moderate to severe paraphimosis is a medical emergency and requires immediate care by a HCP. The longer the problem continues, the greater the risk of circulation problems and possible gangrene. Prevention through daily cleaning and replacing the foreskin to its normal place is important.

**Cancer of the Penis**

Cancer of the penis has been found in men who were not circumcised as infants or adolescents, or who acquired the human papillomavirus (HPV). The tumor is typically a squamous cell carcinoma and may look like a small round raised wart, induration, or red area. This form of cancer can be spread to a sexual partner. Several research studies have found a link between cancer of the penis and cancer of the uterine cervix. Cancer of the penis may be treated with minor surgery, such as a circumcision or laser removal of the growth. If the cancer has spread, sections of the penis may be surgically removed. Penile reconstruction can be done if necessary after surgery. Radiation or chemotherapy may also be done. Finding and treating any lesion in its earliest stages is an important part of patient education, as is education about circumcision of infants as a preventive measure.

**TESTICULAR DISORDERS**

**Cryptorchidism**

Cryptorchidism (undescended testicles) is a congenital condition in which an infant boy is born with one or both of his testicles not in the scrotum. The testicles normally drop down (descend) into the scrotum in the last 1 to 2 months before the boy is born. Often, undescended testicles descend into the scrotum on their own in the first few months of life. If they do not descend by that time, surgery should be done to correct the problem, typically before age 1. Testicles that are not brought down into the scrotum decrease a man’s chances of producing a child, because excessive body heat damages sperm production in the testicles. Also, the risk of testicular cancer is higher if the condition is not corrected before the child reaches his teen years.

**Hydrocele**

A hydrocele is a collection of fluid in the scrotal sac. Hydroceles are not dangerous and generally do not cause pain. The cause is not known, and they can happen at any point during the lifetime. No treatment is necessary unless the hydrocele is so large that it causes discomfort or embarrassment or is a threat to the blood supply to the testicles. If treatment is needed, the HCP can perform a needle aspiration, or surgically drain the fluid.

**Varicocele**

A varicocele is a condition sometimes called varicose veins of the scrotum. The main blood supply to the testicles travels along the spermatic cord. The veins become dilated, and when the man is standing, the area in the scrotum begins to feel like a “bag of worms.” The patient may report a pulling sensation, a dull ache, or scrotal pain. The sensations are most often felt when standing up. Most varicocles occur on the left side because of the way the scrotal vein enters at a sharp angle from the left renal vein. A varicocele is often noted during a routine examination. It is believed that the varicose veins may increase the temperature of the testicles and cause damage to the sperm. The most successful treatment is surgical repair of the varicose veins.

**Epididymitis**

The epididymis is a small tube along the back of the testicles where sperm is matured for its last 10 to 12 days before it is ready to be ejaculated. Epididymitis is inflammation or infection of the epididymis that can be caused by bacteria, viruses, parasites, chemicals, or trauma. Risk factors include sexual or nonsexual contact, STI, a complication of some urological procedures, or reflux (backflow) of urine. The problem can also be associated with prostate infections and is usually painful, with the scrotal skin being tender, red, and warm to the touch.

Epididymitis is treated with antibiotics; the partner is also treated if it was sexually transmitted. Depending on the severity of the pain, the patient may be placed on bedrest with the scrotum elevated, possibly on ice packs, and given analgesics. The pain and tenderness usually go away in about a week, although the swelling may last for several weeks. Complications include chronic epididymitis, abscess formation, and sterility.
Orchitis

Orchitis is a rare inflammation or infection of the testicles. The problem may be caused by trauma or infection from epididymitis, UTI, STI, or systemic diseases such as influenza, infectious mononucleosis, tuberculosis, gout, pneumonia, or mumps (after puberty). The patient has swollen, extremely tender testicles, red scrotal skin, and a fever. Interventions are basically the same as for epididymitis and include bedrest, scrotal support, antibiotics, and medication to relieve pain and fever. Complications such as sterility as a result of orchitis caused by mumps can be prevented by giving boys the mumps vaccine at an early age.

Cancer of the Testicles

Pathophysiology and Etiology

Cancer of the testicles is the most common cancer in men between ages 15 and 34 in the United States. The etiology of testicular cancer is unknown. Some of the known risk factors are cryptorchidism, family history, white race, and high socioeconomic status. Some older studies showed a link between a mother’s use of DES (diethylstilbestrol, an estrogen preparation once used to prevent spontaneous abortion) while pregnant, but current research has not shown this risk to be significant. The tumors are mostly a germ cell type of cancer formed during normal embryo development.

Prevention

The best prevention is early detection with a monthly testicular self-examination (TSE). The American Cancer Society does not necessarily recommend monthly TSE for all men, because not enough studies have been done to show that it reduces death. However, men should be aware of what is normal for them, so they can recognize changes if they occur. The TSE procedure is simple and easy to learn, and it makes sense to teach it to all men until more data are available. See Chapter 41 for instructions on TSE.

Signs and Symptoms

Early warning signs of cancer can include a small, usually painless lump on the testicle. The patient may also notice that the scrotum is swollen and feels heavy. Some tumors produce hormones that cause breast enlargement and tenderness.

Complications

Emotional complications can range from fear of cancer and death to feelings of loss of masculine body image and sexual function. Physical complications may involve dealing with pain and the effects of metastasis to areas such as the lungs, abdomen, or lymph nodes. Other less common areas of cancer spread are the liver, brain, and bone.

Diagnostic Tests

When a lump is found, several laboratory and radiographic tests are done. An ultrasound of the testicles is done first, to differentiate a possible tumor from a hydrocele or other noncancerous condition. Blood is drawn to look for tumor markers. An example of a tumor marker for testicular cancer is human chorionic gonadotropin (HCG). A surgical biopsy or removal of the testicle is done to determine the stage of the tumor. If cancer is confirmed, a chest x-ray examination is done to look for spread to the lungs. A scan of the lymph nodes, liver, brain, and bones also may be ordered.

Testicular tumors may be staged or classified in several ways. The simplest way to stage a testicular tumor is as follows:

- Stage I—tumor only in the testicles
- Stage II—tumor spread to abdominal lymph nodes
- Stage III—tumor spread past lymph nodes, usually to the lungs, liver, bones, and/or brain.

Therapeutic Measures

Intervention depends on the stage of the cancer. All treatment begins with complete removal of the cancerous testicles, spermatic cord, and local lymph nodes. Based on the stage of the cancer, radiation or chemotherapy may be done in addition to surgery. If the cancer is found in the beginning stages, the chances for complete recovery are very good. All patients should have regular follow-up testing.

Nursing Care

Nursing care is directed first at prevention, by teaching young men to practice monthly TSE and to see their HCP if they notice any changes. If a diagnosis of cancer has been made, provide emotional support for the patient. If he wants to have children, he should be encouraged to make deposits in a sperm bank before any surgery or treatment is started. The patient and his partner may have many questions about sexual activities as they go through treatment. Encourage them to talk with their HCP or a sex therapist about ways to express love and tenderness toward one another. Helping patients deal with pain and the side effects of chemotherapy or radiation therapy are also important nursing interventions for these men. See Chapter 11 for care of the patient with cancer.

CRITICAL THINKING

Mr. Cunningham

Mr. Cunningham is a 23-year-old college student engaged to be married next spring. While taking a shower one day, he discovers a lump on his left testicle.

1. What should he do?
2. What are the treatment options if Mr. Cunningham has testicular cancer?
3. How can you help Mr. Cunningham cope with the diagnosis?

Suggested answers are at the end of the chapter.
**SEXUAL FUNCTIONING**

**Vasectomy**

A **vasectomy** uses tiny clamps or cautery to seal off the vas deferens to prevent sperm from reaching the outside of the body (Fig. 43.4). This 15- to 30-minute surgery is done through a small puncture in the upper part of the scrotum. It is performed as a permanent birth control method for men. The patient should carefully discuss the surgery with his physician, so there is a clear understanding of the results following the procedure.

After the procedure, the testicles continue to produce sperm and the male hormone testosterone. The prostate gland, along with the seminal vesicles, still ejaculates semen, but the semen does not contain sperm. There should be no major change in the way the ejaculate looks or feels after the procedure. The patient should be encouraged to continue using another birth control method for about 3 months after surgery to be sure there are no sperm left in the tract above the surgical site. A semen sample should be evaluated for the absence of sperm before the procedure is considered successful. Sperm continue to be produced in the testicles but are absorbed by the body.

**Vasectomy Reversal**

Sometimes a man may decide he wants to have more children and asks to have a vasectomy reversed. The surgical procedure to reverse a vasectomy is called a vasovasostomy. Using microscopic instruments, the surgeon reconnects the vas deferens. If this is not possible, the surgeon may reconnect the vas deferens to the epididymis. During the surgery, the physician typically tries to determine whether the testicles are still producing good sperm. Vasectomy reversal is more successful if it is done soon after the vasectomy. Success rates drop as the period of time between vasectomy and reversal grows longer.

**Erectile Dysfunction**

A problem getting or keeping an erection can happen at any age and has been a concern of men and their partners for centuries. It is a unique problem because it affects not only the man but his partner as well. Most men experience a temporary erection problem at some time during their lives. It is often caused by stress, illness, fatigue, or an excessive use of alcohol or drugs. When the problem becomes persistent, it is time to seek medical help.

Before the 1980s, 90% of men who went to their HCPs for help were told the problem was emotional, not physical. As a result of improved testing methods, however, researchers now believe that 80% to 90% of erection problems have a physical cause.

**Pathophysiology**

The term impotence means powerlessness. This term is being replaced with the more accurate term erectile dysfunction (ED), which describes a physical condition. Erectile dysfunction means that a man cannot obtain or keep a usable erection that is firm enough and long-lasting enough for satisfactory intercourse.
sexual intercourse. For a man to have a usable erection, several conditions must be met:

1. Circulatory system. The blood supply coming into the penis from the arteries must be sufficient to fill the corpus cavernosa (spongy erectile tissue inside the penis), causing the penis to become rigid. The veins in the penis must then be able to constrict to trap the blood in the corporal bodies to keep the penis erect. The most common cause of erectile dysfunction is failure in the circulatory system.

2. Nervous system. Both the sympathetic and parasympathetic nerves are involved in the erection, ejaculation, orgasm, and resting phases of the penile response cycle. There are many nerve receptors and transmitters in the spinal cord and the penis that must be intact for a usable erection. Spinal cord injury is the most common neurologic cause of erectile dysfunction.

3. Hormonal system. There are three basic male hormones involved with an erection. The most important hormone, testosterone, affects a man’s sex drive and desire. Luteinizing hormone stimulates testosterone production, and prolactin in large amounts may block testosterone.

4. Limbic system. This is the center in the brain that affects how we feel emotionally. It works with our five senses to stimulate the desire for sex.

All of these systems can be influenced by physical, emotional, and chemical factors. A good assessment is important to determine the cause of erectile dysfunction.

**Etiology**

ED has many psychological and physical causes. It can also be caused by many medications and chemicals that interfere with desire, blood supply, or nerve transmission (Table 43.3). The most common types of medications that cause problems are those prescribed for high blood pressure and cardiovascular disease. Recently, obstructive sleep apnea has been found to be related to ED, but it is unclear which condition might come first.

**Diagnostic Tests**

In the first step of the assessment process, the HCP obtains a history, including medical-surgical history; use of medications, including any substance abuse; lifestyle patterns; and sexual history. During physical examination, the provider looks for evidence of genital disorders, hormonal imbalance (such as hair patterns or enlarged breasts), surgical interventions, decreased circulation, and lack of nerve sensation. Blood tests evaluate glucose levels; testosterone; evidence of liver, heart, or kidney disorders; signs of infection; or blood disorders. Some HCPs may use intracorporeal injection of vasoactive medications that can create an erection to test the blood flow in the penis. A psychosocial evaluation may be recommended to rule out relational or emotional problems that may contribute to erectile dysfunction or affect the treatment outcome.

*Note: Not all drugs in a category cause erectile dysfunction.

A second level of testing may involve the use of sophisticated vascular flow studies to locate areas where either the blood vessels are narrowed or the veins allow the blood to drain out of the penis too rapidly. Another area of testing monitors erections during sleep. A healthy man typically has erections every 60 to 70 minutes while he sleeps. Absence of erections during sleep indicates a physical cause for erectile dysfunction. Because of the expense of vascular flow studies and sleep studies, they are used on a limited basis.
**Therapeutic Measures**

One of the most important treatment options begins with the couple being able to share intimate communication. No matter what is causing the problem, if the patient and his partner are not touching, talking, and sharing feelings with one another, treatment options are going to have limited success.

When the problem has clearly been identified as psychological, counseling therapy is the treatment of choice. If long-term therapy has been tried with only limited success, the addition of oral medication or even intracorporeal injection therapy may be added to provide a boost in confidence and self-esteem. Medical treatment for physical erection problems begins with conservative, nonsurgical treatment and then progresses to surgical options if needed. See Table 43.1 for additional information on medications.

**MEDICATION CHANGES.** Sometimes all that is needed to correct the problem is a change in medication. It is important for the patient to talk with the HCP before stopping any medication. Some men have stopped taking their blood pressure medication and risked a stroke or heart attack because it interfered with their sexual activity.

**ORAL MEDICATIONS.** Oral medications (sildenafil [Viagra], tadalafil [Cialis], and vardenafil [Levitra]) are now the first line of therapy used to treat erectile dysfunction. These medications cause the arterioles and cavernous tissue to relax, allowing more blood to flow into the penis in response to sexual stimulation. The pill is usually taken 30 to 60 minutes before anticipated sexual intercourse. Men using nitrate medication (antianginal agents) should avoid using the pills because of risk for severe low blood pressure.

**HORMONE TREATMENT.** If the testosterone level is low, replacement hormone may be needed. The HCP should first examine the patient carefully for any evidence of prostate cancer because testosterone replacement can cause the cancer to grow and spread. Testosterone replacement can be given by intramuscular injection, topical gel, or transdermal patch. Testosterone levels must be monitored closely for both positive and negative side effects.

**HERBAL REMEDIES.** Several herbal remedies may be effective, including yohimbine, dehydroepiandrosterone (DHEA, a steroid hormone), ginseng, ginkgo, and others. Herbal remedies have side effects, just like prescription medications, and should not be taken without a HCP’s recommendation.

**INJECTED MEDICATION.** After careful evaluation, a patient or his partner may be taught how to inject a medication into the penis using a 26- or 27-gauge needle on a tuberculin syringe or a prefilled autoinjector. The injections are nearly painless and produce a natural erection in 10 to 15 minutes. The most serious side effect is priapism, which requires immediate reversal in a physician’s office or emergency room.

**TRANSURETHRAL SUPPOSITORY.** To facilitate medication dispersion and absorption, a patient may choose to use a suppository. The patient is instructed to urinate before use of the suppository. A tiny pellet (microsuppository) is inserted into the urethra using a specialized single-dose applicator. The medication usually begins to work in 5 to 10 minutes, and the effects last for about 30 to 60 minutes.

**OTHER NONSURGICAL TREATMENTS.**

**Sexual Devices and Techniques.** A variety of mechanical sexual aids can be considered by patients who do not want or cannot afford expensive medical treatment. Men should be encouraged to talk with a HCP or qualified sex therapist before trying these alternatives.

Suction devices are another nonsurgical treatment option. This is an external cylinder vacuum device that fits over the penis and draws the blood up into the corporeal bodies, causing an erection. A penile ring is then slipped onto the base of the penis. Once the cylinder is removed, sexual intercourse can begin. Special care must be taken to remove the penile ring within 15 to 20 minutes to prevent tissue damage.

**SURGICAL TREATMENTS.**

**Penile Implants (Prostheses).** Penile implants are a pair of solid or fluid-filled chambers that are surgically placed into the corporeal bodies in the penis to produce an erection. There are two basic types of implants—noninflatable and inflatable (Fig. 43.5).
**Vascular Surgery.** If a younger man has an erection problem caused by poor blood flow into the penis or from blood leaking out of the penis, rapidly causing the loss of the erection, corrective surgery may be performed. A bypass graft may be done to increase blood flow into the penis or to go around a blockage (as occurs, for example, with Peyronie’s disease).

**Nursing Process for the Patient With Erectile Dysfunction**

**DATA COLLECTION.** Your role as a nurse may vary based on your work setting. It is always appropriate to ask a man if he has any concerns related to sexual health. It may open the door for him to talk further. It is important to provide privacy and ensure confidentiality. Ask history questions about possible psychosocial causes, including use of medications, street drugs, alcohol, or nicotine. If a problem is identified, alert the HCP, who will continue a more thorough assessment.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION. Readiness for Enhanced Self Health Management related to treatment of sexual dysfunction**

**EXPECTED OUTCOMES:** The patient will verbalize understanding of the cause and treatment options for erectile dysfunction.

- Determine patient and partner’s current knowledge and understanding about cause and treatment of the disorder. *This will allow for additional and/or correct information to be provided about sexual dysfunction for appropriate understanding.*
- Provide patient and partner with additional and/or correct information about cause and treatment of disorder. *This will allow the patient to have a full understanding of the etiology and care related to the disorder, and increase likelihood of patient adherence to and success of treatment.*
- Refer patient and partner (as appropriate) for medical treatment, psychological treatment, or counseling. *An individualized treatment plan (determined by the etiology) is needed to move toward restoration of sexual functioning.*

**EVALUATION.** The best indicator of a positive outcome is restoration of erectile function with a verbal account of understanding the disorder and satisfaction with the treatment process. Sometimes the physical problem is easier to correct than the emotional scars that the problem has created. It is important to evaluate both the physiological and emotional outcomes of treatment.

**PATIENT EDUCATION.** The nurse plays an important role in public education related to erectile dysfunction. Men need to know that they are not alone with their problem. More than 30 million men in the United States experience ongoing problems with erections. Usually, the cause is physical, and help is available through HCPs who specialize in treating erectile dysfunction. See Table 43.4 for a summary of male sexual dysfunction.

**CRITICAL THINKING**

**Mr. Kittle**

- Mr. Kittle presents to the clinic saying that he is not able to sustain an erection long enough for sexual intercourse that is satisfactory for himself and his partner.

1. You have never had a patient tell you his sexual problems, and you feel a little uncomfortable. How should you respond?
2. What will your assessment include?
3. What is an appropriate role for the LPN/LVN in helping Mr. Kittle?

*Suggested answers are at the end of the chapter.*

**Infertility**

A growing number of couples in the United States are having difficulty conceiving children. Several factors can interfere with a man’s ability to father a child.

**Physiology**

A number of conditions must be present in the man for conception to occur. Endocrine function, autonomic nervous system function, and male reproductive structures must all be functioning properly. Normal healthy sperm in a concentration of at least 20 million per milliliter of semen are needed.

**Etiology**

The factors related to infertility are divided into three general categories: pretesticular, testicular, and post-testicular.

**PRETESTICULAR (ENDOCRINE) FACTORS.** The first factor involves the proper functioning of the hypothalamus, the
UNIT ELEVEN Understanding the Genitourinary and Reproductive System

pituitary gland, and the testicles. These endocrine functions are complex and are a rare cause of infertility. Examples of endocrine causes might be pituitary or adrenal tumors, thyroid problems, or uncontrolled diabetes.

**TESTICULAR FACTORS.** The two most common causes of male infertility are varicoceles (40%–50%) and idiopathic causes (40%). It is believed that a varicocele lowers the sperm count by raising the blood flow and temperature in the testicles. Sperm cannot live if the temperature is too high or too low.

Congenital anomalies such as Klinefelter’s syndrome (a chromosomal defect) or cryptorchidism result in absent or damaged testicles. Certain disease or inflammatory processes may cause damage to the storage area (epididymitis) or to the testicles themselves (mumps orchitis). Any high fever or viral infection can interfere with the production of sperm for up to 3 months.

Medications, radiation, substance abuse, environmental hazards, and lifestyle practices have all been identified as possible factors that can interfere with spermatogenesis (sperm production). Excessive use of hot tubs and saunas, wearing tight jeans, and long-haul truck driving have all been identified as raising the temperature level in the scrotum to the extent that sperm production is decreased.

**POST-TESTICULAR FACTORS.** The most common factor in post-testicular infertility is the result of surgery or injury along the pathway from the testicles to the outside of the man’s body. Examples of surgical causes are vasectomy, bladder neck reconstruction, pelvic lymph node removal, or any surgery that causes retrograde ejaculation. Congenital anomalies and various types of infections may also cause infertility problems.

**Prevention**

Prevention involves possible lifestyle changes to avoid excessive heat to the scrotum, substance abuse, exposure to toxins, and environmental hazards. Problems related to medication or infections should be discussed with the HCP.

**Signs and Symptoms**

A couple is considered infertile if they have been unsuccessful at becoming pregnant after at least 1 year of unprotected intercourse. If pregnancy has occurred during the year but there was no delivery, the problem usually is considered a female rather than a male factor.

**Diagnosis**

Diagnosis begins with a detailed history and physical examination that looks for known male causes of infertility.

**HISTORY.** Initial assessment includes frequency of intercourse, timing (according to ovulation cycle), use of contraceptives, problems with premature ejaculation, and erection problems.

Use of hot tubs or saunas; tight jeans; use of nicotine, caffeine, alcohol, or marijuana; and the desire for children on the part of the man are all assessed. High stress, long periods of sitting, and exposure to environmental toxins are determined. The patient also may be questioned about STIs, endocrine problems, congenital urinary problems, serious illnesses or groin injuries, cancer, and treatment with chemotherapy or radiation.

**PHYSICAL EXAMINATION.** The HCP will observe for normal hair pattern and growth, muscle development, size of testicles, and any evidence of a varicocele or hydrocele.

**DIAGNOSTIC TESTS.** Analysis is done on several semen specimens to see if they contain the right amount and type of healthy sperm needed for a pregnancy. Infection should be ruled out. Several other tests may be done, including hormone tests, genetic testing, ultrasound, and others, depending on the level of desire and the financial resources of the couple. Many insurance companies do not pay for testing or treatment for infertility.

**Therapeutic Measures**

Treatment may be as simple as making a change in sexual or lifestyle practices. Surgery to correct a varicocele or obstruction may be done. If the couple is able to handle the emotional and financial strain, they may try a variety of in vitro fertilization (IVF) procedures. IVF is very costly, and success rates vary. Another option that may be presented to the couple is adoption.

You can play an important role in the emotional support a couple needs during infertility studies. It is important that the couple feel comfortable in communicating their feelings and frustrations with one another and their HCP. It also may help them to attend a support group designed for couples experiencing infertility.

---

**SUGGESTED ANSWERS TO CRITICAL THINKING**

**Mr. Atkinson**

1. \[ \frac{5 \text{ mg}}{1 \text{ tablet}} \times \frac{1 \text{ tablet}}{2 \text{ mg}} = 2.5 \text{ tablets} \]

2. Mr. Atkinson should be alert for signs of hypotension, such as dizziness or lightheadedness on arising. He should not drive until effects and side effects of the medication are known.

3. Mr. Atkinson should be instructed not to lift anything heavier than 10 lb for the first 6 weeks, and he will not be able to plow or drive for the first 6 weeks. It is important that his son understand his father’s limitations and how important it is for him or someone else to help out with the farm chores.
Review Questions

1. A patient with benign prostatic hyperplasia expresses concern that he has cancer. Which response by the nurse is best?
   1. “Don’t worry; prostatic hyperplasia is not the same thing as cancer.”
   2. “Since it is called benign, you don’t have to worry about it. No treatment should be necessary; you will just need to have it watched.”
   3. “Hyperplasia means your prostate is growing too many cells. They are not cancerous, but they could interfere with your ability to urinate, so it is important to have it treated.”
   4. “You are correct, it is a form of cancer, but it is very slow growing and very treatable. Your doctor will recommend treatments for you.”

2. A nurse is discharging a man from the emergency department after treatment for priapism. Which statement by the patient shows understanding of instructions?
   1. “I should use hot packs three times a day for the next three days.”
   2. “I should be seen immediately if I have another erection lasting more than 2 hours.”
   3. “The Viagra I took may have caused this problem.”
   4. “I should avoid having sex for one month.”

3. A patient who is 1-day post–transurethral resection of the prostate says he is having pain in his bladder, and the nurse notices urine leakage around his catheter. Which of the following responses by the nurse is best?
   1. “Bladder spasms are common after your surgery. Take some deep breaths while I get a B&O suppository.”
   2. “You should not be experiencing spasms. I will notify the RN right away.”
   3. “Spasms can be very painful. Would you like an injection of Demerol?”
   4. “Your catheter is leaking; we will need to replace it right away.”

4. A nurse working in a nursing home notes that it is difficult but not impossible to retract the foreskin for cleaning on an older gentleman. Which action is correct?
   1. Avoid retracting the foreskin for cleaning to prevent paraphimosis.
   2. Gently retract the foreskin for cleaning, then replace it and notify the HCP.
   3. Retract the foreskin for cleaning, and leave it retracted to prevent infection.
   4. Retract the foreskin and leave it retracted until the HCP can evaluate it.
5. Which statement by a patient shows the need for more education about erectile dysfunction?
   1. “I may have blood flow problems that are causing the dysfunction.”
   2. “I can try some herbal remedies such as ginseng before consulting my physician.”
   3. “Some men inject drugs into their penis to cause an erection.”
   4. “My sleep apnea could be a factor in erectile dysfunction.”

6. A patient is admitted to a medical unit for complications of diabetes. The nurse asks if he is satisfied with his level of sexual functioning, and he becomes tearful. Which initial response by the nurse is best?
   1. “You seem upset with my question. Are you having a problem you would like to talk about?”
   2. “Impotence is common with diabetes. Don’t let it worry you.”
   3. “What kind of sexual dysfunction are you experiencing?”
   4. “I am sorry you are having problems with your sexual functioning. Would you like a referral to a sex therapist?”

7. What are common complications of varicocele? Select all that apply.
   1. Infertility
   2. Infection
   3. Erectile dysfunction
   4. Pain
   5. Priapism
   6. Cancer

8. Which of the following should the nurse anticipate teaching about when caring for a man with infertility?
   1. Penile implants
   2. Prostatectomy
   3. TURP
   4. Decrease in nicotine and alcohol use

Answers can be found in Appendix C.

LEARNING OUTCOMES

1. Identify the pathogens involved with each of the common sexually transmitted infections (STIs).
2. Describe the signs and symptoms of each of the common STIs.
3. Plan teaching to promote STI prevention.
4. Describe treatment options for common STIs.
5. Plan nursing care for patients with STIs.
6. Explain how you will know if your nursing interventions have been effective.

vesicular (veh-SIK-yoo-lur)
vulvovaginitis (VUL-voh-VAJ-ih-NY-tiss)
Sexually transmitted infections (STIs) are infections that can be transmitted through intimate contact with the genitals, mouth, or rectum of another individual. Some STIs can also be spread by other routes such as blood or body fluids. A nurse’s best protection against catching diseases from blood and body fluids of infected patients is the strict practice of standard precautions and maintaining his or her own healthy, intact skin.

Physically, STIs can cause tremendous suffering through pain, scarring of genitourinary structures, damage to other body organs, infertility, birth defects, nervous system damage, development of cancer, and even death of infected patients and sometimes their children. Psychologically and socially, these infections also have profound effects on individuals, families, and relationships. Guilt about passing on an incurable infection to a loved one or feelings of betrayal because of being infected as a result of someone else’s choices are some of the emotional consequences of STIs.

Changing social values have been associated with increasing incidence of almost all types of STIs, including some previously rare infections related to anal intercourse. Coexistence of more than one STI in an individual is also occurring more often. Many infections and syndromes are associated with STIs; the more common ones are discussed here. Human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) are discussed separately in Chapter 20.

One of the most important ways you can help those who experience STIs is by being kind, nonjudgmental, and sensitive to the patient’s communication. Maintaining an open posture and eye contact that is appropriate for the patient’s culture relays a sense of openness and willingness to talk and preserves the possibility of continuing health promotion with these individuals in the future.

**Disorders and Syndromes Related to Sexually Transmitted Infections**

**Vulvovaginitis**

Vulvovaginitis is an inflammation of the vulva and vagina and can be asymptomatic or involve redness, itching, burning, excoriation, pain, swelling of the vagina and labia, and discharge. A variety of sexually and nonsexually transmitted infectious agents can cause vulvovaginitis. The odor, consistency, and color of the discharge vary with the different microbes involved. Nonsexually transmitted vaginitis, vulvovaginitis, and vaginosis are described in Chapter 42. Some microorganisms may be acquired either by sexual or nonsexual routes, so they are also mentioned in this chapter. Bartholin’s glands can develop abscesses as a result of infection with nonsexually transmitted microbes or STIs such as gonorrhea and chlamydia.

**Urethritis**

Both STIs and nonsexually transmitted microorganisms can cause urethritis in men and women. In men, inflammation of the urethra, prostate, and epididymis can result in difficulty, painful, and frequent urination and a urethral discharge, which may be clear, cloudy, or yellow. Female partners of men with urethritis may also suffer from urethritis, and they may also develop mucopurulent cervicitis (MPC) and a variety of other symptoms of the particular infection. Some causative agents for urethritis include Neisseria gonorrhoeae, Chlamydia trachomatis, Ureaplasma urealyticum, Trichomonas vaginalis, Candida albicans, and herpes simplex. Often this infection category is divided into gonococcal urethritis caused by N. gonorrhoeae and nongonococcal urethritis.

**Mucopurulent Cervicitis**

MPC is an inflammation of the cervix that may produce a mucopurulent yellow exudate on the cervix or may have no noticeable symptoms. MPC during pregnancy can result in conjunctivitis and pneumonia in newborn infants, as well as puerperal infection of the mother. MPC can be caused by such organisms as C. trachomatis, N. gonorrhoeae, T. vaginalis, C. albicans, and herpes simplex. MPC may spread to become pelvic inflammatory disease (PID).

**Proctitis and Enteritis**

Proctitis is inflammation of the rectum and anus that may be due to either nonsexually transmitted microbes or STIs. This is especially prevalent among those who practice heterosexual or homosexual anal intercourse. Enteritis, which is inflammation of the lining of the intestine, may occur as a result of contamination during anal intercourse. Infection with Campylobacter species, Shigella species, and Giardia lamblia can be a problem for gay men. Care of patients who have gastrointestinal disorders is discussed in Unit 8.

**Genital Ulcers**

Genital ulcers are formed when papules or macules erode and leave painful, raw, pitted, or excoriated areas on or around the genitals. Not all genital ulcers are caused by STIs—injury some...
non-STI viruses, some types of drug reactions, radiation, and some forms of cancer can also produce genital ulcers. STIs that can produce genital ulcers include syphilis, herpes, and HIV. Although the ulcerations can look similar in these STIs, a distinctive difference is that a syphilitic ulcer is painless. Genital ulcers from one type of disease may increase the risk of infection with other STIs during sexual activity because the open areas present an easy portal of entry for the infecting organism.

**Cellular Changes**

Cellular changes can also be caused by STIs, including condylomatous (wartlike) growths and dysplasia or neoplasia, which may result in precancerous or cancerous conditions. Herpes viruses, HIV, and human papillomavirus (HPV) have all been linked to the development of cancer.

**Pelvic Inflammatory Disease**

**Pathophysiology and Etiology**

PID is an infection of the upper genital tract that can cause chronic pelvic pain due to inflammation. The primary source of infection include *C. trachomatis* and *N. gonorrhoeae*, but it may result from any organism that is associated with a STI. These organisms can invade the endocervical canal, resulting in cervicitis, and move upward resulting in infection of the endometrium (endometritis), fallopian tubes (salpingitis), and pelvic cavity. The chronic inflammation results in extensive scarring and adhesions, which can cause infertility and increase the risk of ectopic pregnancy. Increased risk for PID occurs with a history of multiple sexual partners, STIs, substance abuse, frequent vaginal douching, and insertion of an intrauterine device (IUD). Testing for STIs and treatment before insertion of an IUD greatly reduces the risk of PID.

**Signs and Symptoms**

Some women with PID are asymptomatic or have minimal symptoms. Other women present with lower abdominal pain and tenderness, purulent vaginal discharge or vaginal bleeding, pain with sexual intercourse, fever, nausea and vomiting, and pain with urination. Findings during physical examination include adnexal tenderness upon palpation, and pain in the uterus and cervix when moved during a bimanual examination.

**Diagnostic Tests**

Laboratory tests may reveal a positive culture of the causative organism(s) and leukocytosis. Urinary tract infection may need to be ruled out.

**Therapeutic Measures**

With serious infection, hospitalization and intravenous (IV) antibiotics may be indicated. IV therapy can be changed to oral therapy after 48 hours if status improves. Outpatient therapy with oral antibiotics is used with minor infections. Laparoscopic surgery may be done to release adhesions and reduce complications. Testing and treatment for other STIs should be considered for both the patient and her partner. Education on the cause of the infection and prevention of future episodes is essential.

*Continued*
via contact with other mucous membranes, or through contact with blood and body fluids. It can produce a variety of signs and symptoms. Men may be asymptomatic or may have urethritis with a yellow urethral discharge. Women who have gonorrhea may have either no noticeable symptoms or have sore throat, MPC, urethritis, or abnormal menstrual symptoms such as bledding between periods. Many cases of PID are caused by gonorrhea. Intercourse with an infected partner during menstruation may be especially risky for development of PID because removal of the cervical mucous barrier can promote the growth of the gonococcus in the higher reproductive tract. Gonorrhea can also cause Fitz-Hugh-Curtis syndrome. Fever, nausea, vomiting, and lower abdominal pain may be present. Gonorrhea may also infect the throat and the rectum and may cause disseminated gonococcal infection, resulting in inflammation of the joints, skin, meninges, and lining of the heart.

Newborns born to mothers who have gonorrhea can develop ophthalmia neonatorum, which involves inflammation of the conjunctivae and deeper parts of the eye and can, ultimately, result in blindness. The newborn may also experience a gonorrheal infection at other sites follo wing birth. Abscesses may develop where fetal scalp monitors were attached during labor, and infection of the nose, lungs, and rectum may occur.

**Diagnostic Tests**

Diagnosis is done by microscopic examination of smears and cultures of the discharge or identification of bacterial DNA (nucleic acid testing) in the urine. More than one test may be done to verify the diagnosis.

**Therapeutic Measures**

Development of antibiotic resistance by *N. gonorrhoeae* and co-infection with other microorganisms, such as *C. trachomatis*, is making treatment more complicated. Cephalosporin antibiotics are recommended for the treatment of gonorrhea (see Table 44.2). It is also recommended that the patient be treated for chlamydia because co-infection is common. Ophthalmia neonatorum can be prevented by use of antibiotic eye preparations that contain silver nitrate, erythromycin, or tetracycline. It is recommended, as with prophylactic treatment of chlamydial conjunctivitis, that all infants be treated shortly after birth regardless of diagnostic status of the mother. The treatment is simple and may prevent a devastating outcome for the newborn. Institutional policies and state regulations determine the type of eye drops to be used and whether administration of the drops requires specific consent of the parents.

**CRITICAL THINKING**

*Mrs. Miller*

- Mrs. Miller delivered an infant boy 1 hour ago. The nurse is currently applying erythromycin ointment to the infant’s eyes bilaterally. Mrs. Miller asks if the medication is necessary.

1. How will you respond?
2. Should all infants receive prophylactic eye treatment at birth?

*Suggested answers are at the end of the chapter.*

**Syphilis**

*Pathophysiology, Etiology, and Signs and Symptoms*

Syphilis is an ancient infection that has not disappeared, although it is overshadowed by more commonly occurring
infections such as chlamydia. It occurs in stages. The primary stage of syphilis begins with the entry of Treponema pallidum spirochete through the skin or mucous membranes. Between 3 and 90 days later, a papule develops at the site of entry, then sloughs off, leaving a painless, red, ulcerated area called a chancre (Fig. 44.1). Chancre formation typically is the only symptom of this stage of syphilis. The chancre eventually heals, but the spirochete remains active in the infected individual and can be passed on to others.

Secondary syphilis begins 2 to 8 weeks later and affects the body more generally, causing such problems as flu-like symptoms, joint pain, hair loss, skin rashes (primarily on the soles of the hands and feet), mouth sores, and condylomatous growths in moist areas of the body.

Serious damage can occur if syphilis is untreated in the early stages. About 15% of infected individuals will progress to the tertiary (or late) stage, up to 10 to 20 years later. At this stage, it can involve any organ system of the body. The spirochete can form gummas, which are tumors of a rubbery consistency that can break down and ulcerate, leaving holes in body tissues. The gummas can damage the heart, circulatory system, and nervous system (called neurosyphilis). Ulceration of gummas can destroy areas of vital tissue and lead to mental and physical disability or early death.

Syphilis can be passed on to the unborn children of women who carry the spirochete, resulting in hepatosplenomegaly, increase in bilirubin, destruction of red blood cells, birth defects (especially of the face), lymphadenopathy, and a baby who can transmit the spirochete through nasal drainage. If left untreated, syphilis during pregnancy can cause lesions in various organs of the unborn baby and result in higher rates of spontaneous abortion, stillbirth, and premature birth.

Diagnostic Tests

Several tests for syphilis exist, and a combination may be used for accurate diagnosis. Cultures may be done but are difficult to grow. Serological (blood) tests include the venereal disease research laboratory (VDRL) test, the rapid plasma reagin (RPR) test, and the automated reagin test (ART). These tests indirectly check for syphilis by detecting the presence of antibodies that the body forms in response to Treponema and, unfortunately, in response to some other disorders, so false-positive results can occur. Diagnosis of neurosyphilis is even more difficult because some testing of cerebrospinal fluid may result in false-negative results. Treponema enzyme-linked immunosorbent assay (ELISA), fluorescent treponemal antibody absorption (FTA-ABS), and polymerase chain reaction (PCR) tests for treponemal DNA are some newer methods that reduce the risk of false results.

Therapeutic Measures

Penicillin G is the treatment of choice for patients diagnosed with syphilis (see Table 44.2). For those who are allergic to penicillin, doxycycline and tetracycline are treatment options. When HIV and syphilis are diagnosed in the same individual, symptoms of neurosyphilis are more likely to occur.

Trichomoniasis

Pathophysiology and Etiology

Trichomoniasis is an STI caused by a protozoan parasite. It can be also be transmitted through nonsexual contact with infected articles because it can survive for a long time outside the body. Carriers of Trichomonas vaginalis can be asymptomatic for several years until changes in vaginal or urethral conditions encourage an outbreak of the infection. A decrease in resident bacteria, injuries to the vaginal tissues, and development of lesions from other STIs or from some forms of cancer can activate the organism.

Signs and Symptoms

Symptoms include redness, swelling, itching, and burning of the genital area; pain with intercourse and voiding; and a frothy, foul-smelling discharge that can be clear, white, yellowish, or greenish. Men with trichomonal infection can develop prostatitis and infertility. Men who are also infected with HIV are more likely to transmit HIV to others, and women with Trichomonas vaginalis are more susceptible to HIV infection if exposed. Women who are pregrant risk preterm delivery and low birth weight babies.

Diagnostic Tests

A Papanicolaou (Pap) test can be used to diagnose trichomoniasis. Visualization of the cervix during pelvic examination shows a characteristic “strawberry cervix.” When wet-mount slides of discharge are viewed under a microscope, the...
organisms can be identified by their motility and whip-like flagella. Because trichomoniis can produce abnormal Pap smear readings, more frequent Pap smears must be done to provide adequate surveillance of cellular changes.

**Therapeutic Measures**

Antiparasitic agents metronidazole (Flagyl) or tinidazole (Tindamax) are used to treat trichomoniis (see Table 44.2). Because some people carry the organism without symptoms, sexual partners should also be treated regardless of symptoms.

**Herpes**

**Pathophysiology, Etiology, and Signs and Symptoms**

Herpes infection is caused by the herpes simplex virus types 1 and 2 (HSV-1 and HSV-2). Herpes viruses have an affinity for tissues of the skin and nervous system and can lie dormant in nervous system tissues and then reactivate periodically when the body undergoes stress, fever, or immune system compromise. Both HSV-1 and HSV-2 can cause “fever blisters” of the mouth (Fig. 44.2), as well as genital lesions. However, HSV-1 is more frequently associated with oral lesions and HSV2 with genital lesions.

Genital HSV-2 outbreaks are more severe than genital HSV-1 outbreaks. After infection, vesicles develop, spontaneously rupture, and produce painful ulceration of the underlying skin tissues. Asymptomatic latent periods are generally interspersed between the vesicular outbreaks. Although not as common, the virus may still be transmitted even during latent periods.

An initial outbreak following infection with the herpes virus occurs 2 days to 2 weeks after exposure and can produce a flulike condition. Urethritis, cystitis, and MPC with vaginal discharge can also occur. Infection of the spinal nerve roots by HSV can result in sacral radiculopathy (damage of the sacral spinal nerves), causing retention of urine and feces. Although rare, disseminated herpes infection can result in inflammation of the spinal cord, meninges, nerve pathways, and lymph nodes; urethral strictures; and increased risk for development of cervical cancer in women.

It is estimated that one in five of all pregnant women carry herpes, although most of their babies do not develop herpetic disease. If infected, the baby’s skin, eyes, mucous membranes, and nervous system can be involved, and death from disseminated herpes infection is possible. The greatest risk of herpes transmission from mother to child during pregnancy occurs if the mother has an active genital lesion at the time of delivery.

**Diagnostic Tests**

Testing for HSV requires special viral collection kits for swabbed or scraped specimens from lesions. Follow the directions on the viral collection kit as well as institutional policies. Blood tests are used to test specifically for HSV-1 or HSV-2 antibodies.

**Therapeutic Measures**

There is currently no known cure for herpes infection, although antiviral medications may be given to decrease the severity of symptoms (see Table 44.2). Pregnant women with a history of HSV are treated prophylactically with antiviral medication during the last 36 weeks of pregnancy (CDC, 2013b). If an active genital lesion is present when a woman is close to the time of delivery, a cesarean delivery is likely to be performed. However, an active lesion at any time during pregnancy poses a risk for transmission. See the “Nursing Care Plan for the Patient With an STI” later in this chapter.
Genital Warts

Signs and Symptoms

Condylomata acuminata (genital warts) is a common sexually transmitted viral infection, and its incidence is increasing rapidly. Infection with human papilloma virus (HPV) produces the condylomata—soft, raised, verrucous fleshy tumors, which may also have finger-like projections and resemble cauliflower (Fig. 44.3). Lesions most commonly develop on the external genitalia and perineum, as well as on the internal vaginal wall and cervix in women. However, lesions can also develop on other areas of the body after contact with the virus. Some people remain asymptomatic, but can still transmit the infection.

More than 100 types of HPV have been identified, and several have been closely linked to the development of cancers of the reproductive organs and anus in both males and females. The latent period from the time of exposure to development of the warts can be as long as 3 years.

HPV can be passed on from a pregnant woman to her fetus, resulting in the growth of genital warts on the baby, HPV infection of the baby’s respiratory tract, and a possible future increased risk of cancer development. HPV infection during pregnancy can cause particularly difficult problems. Genital warts tend to grow more rapidly in pregnant women and to ulcerate and slough over a long period. Wart removal does not cure the infection, and new wart growth can occur after treatment.

Diagnostic Tests

Diagnosis can be made by applying dilute acetic acid (vinygar) to the skin of the external genital area, vagina, cervix, and anus and then closely examining with a colposcope for areas that turn a lighter color. Biopsy specimens of the suspicious areas can be sent for further study of the cells. Other tests to diagnose HPV include an antigen test and the Southern and dot blot tests, which use radioactive probes. Cancerous changes stimulated by the virus may be identified on Pap smears.

Therapeutic Measures

There is currently no known cure for papillomavirus infection. The warts can be treated by freezing, burning, or chemically destroying them or by manipulating the patient’s immune system to attack the virus. Cryotherapy (freezing) of the warts can be done by touching each wart with a cryo-probe or a liquid nitrogen–soaked swab. Warts may also be burned or electrocoagulated with an electrocautery or a laser. Heat causes the proteins to coagulate, resulting in death of the wart tissue. Several topical agents are also available (see Table 44.2).

Some treatment options are not appropriate for use during pregnancy because of their cytotoxic effects, which might damage the fetus, but cryosurgery and laser destruction of wart tissue can be done during pregnancy. All treatments may require multiple applications and generally result in a great deal of discomfort as the warts degenerate, ulcerate, and slough over a long period. Wart removal does not cure the infection, and new wart growth can occur after treatment.

Various types of immunotherapy have been used against HPV. Interferons are proteins produced by the body that can inhibit viral growth. Several types of interferons have been used to combat HPV. These substances can be applied topically, injected into the condyloma, or administered systemically. Interferons can produce side effects of flu-like symptoms, a drop in the number of white blood cells, and changes in her function. Systemic interferon treatment, however, may offer the advantage of being able to attack warts all over the body at the same time, rather than individually as with topical treatments, thus speeding the process of treatment.

Research to develop vaccines against HPV strains is ongoing, but the multitude of varieties makes this difficult. The Gardasil vaccine was introduced in 2006 for the prevention of four types of HPV. Gardasil protects against the low-risk types of HPV, 6 and 11, which cause 90% of genital warts. Gardasil also protects against high-risk types 16 and 18, which are known to cause 70% of cervical cancers. Women and men ages 9 through 26 receive three doses of the vaccine, starting with the initial dose, then again at 2 and 6 months after the initial dose. The vaccine does not prevent many of the other types of both high- and low-risk HPV.

Home Care

Patients who have genital warts (condylomata acuminata) burned off need to recuperate at home. Multiple areas may be

Signs and Symptoms
Early signs of hepatitis are loss of appetite, rashes, malaise,
muscle and joint pain, headaches, nausea, and vomiting. Because the virus affects the liver, the urine may darken and the stool color may lighten (as a result of changes in bile excretion), liver enzymes may rise, and jaundice may appear. Enlargement of the spleen, enlargement and tenderness of the liver, necrosis of liver cells, cirrhosis, coma, and death may follow if the disease is severe. Chronic asymptomatic carrier status can follow hepatitis virus infection, with an increased risk of liver cancer.
Diagnostic Tests
Diagnosis of hepatitis is generally made using a variety of blood tests based on antigen and antibody responses. A blood test for liver enzymes and liver biopsy may be done to determine the extent of liver damage.
Therapeutic Measures
If a person is aware of being exposed to HBV, hepatitis B immune globulin can be injected within 24 hours to provide
Genital Parasites
Etiology and Signs and Symptoms
Genital parasites are not a true STI, but they may be transmitted during close body contact. The two most commonly seen parasites are pubic lice (Phthirus pubis, commonly called “crabs” because of the shape of the lice) and scabies (Sarcoptes scabiei). These parasites cause itching, redness, and, for scabies, tracks under the skin where the females burrow to lay their eggs.
Diagnostic Tests
History, physical examination, and direct visualization or magnified view of the parasites aid in diagnosis.
Therapeutic Measures
Parasites are treated with topical insecticides such as permethrin (Elimite, Acticin, for scabies) or malathion (Ovide, for pubic lice). Advise the patient to refer to package inserts for application instructions and precautions to avoid reinfection.

REPORTING OF SEXUALLY TRANSMITTED INFECTIONS
The nurse may be required to facilitate the reporting and public health follow-up of STIs by filling in patient information on an STI reporting form and placing the form in the patient’s chart for completion by the HCP. The requirements for reporting STIs may vary for different states, provinces, and countries. In some areas, laboratories are also required to submit a report form for positive reportable STI results. Laboratory reports that are not followed by an HCP’s report may result in investigation by an STI investigator. Generally, the report form has spaces for listing of sexual contacts that should be notified of possible STI exposure. Depending on the laws of the state, province, or country, HCPs may notify identified sexual contacts, or patients may do so themselves. Contacts may also be notified by a public health authority that they have been listed as a sexual contact by an anonymous person who has tested positive for an STI.

NURSING PROCESS FOR SEXUALLY TRANSMITTED INFECTIONS
Data Collection
STIs are usually assessed, diagnosed, and treated in HCPs’ offices and in clinics. It is important to evaluate the patient’s reason for seeking health care with every
outpatient visit. Sometimes patients visit clinics or HCPs’ offices for stated reasons other than STIs, yet their real concern is an STI.

If a patient presents with signs and symptoms that could lead to an STI diagnosis, inquire about whether he or she currently has any irritation, pain, lesions, or discharge in the genital region. Explaining to the patient the need to know what examination supplies to prepare for an appropriate assessment, may allow him or her to share concerns and true reasons for the visit. Establishing rapport and conveying acceptance may also facilitate communication. Often the nurse is present during the examination to assist the HCP and to serve as a chaperone or patient support person.

STIs may also be discovered in hospitalized patients. Nurses are often the ones who bathe and provide perineal care to patients. It is important to be aware of signs and symptoms in older adults as well as younger people (“Gerontological Issues”). Unusual discharge, redness, blisters, swollen areas, ulcers, and evidence of parasites in the genital area may be observed during patient care. STI awareness can also sensitize you to the possible significance of patient reports of persistent pelvic pain, dysuria, discharges, and rectal soreness. Such problems should be accurately documented and reported, so that further investigation and possible treatment can take place.

Continued
NURSING CARE PLAN for the Patient With Genital Herpes

**Nursing Diagnosis:** Acute Pain related to inflammation and skin lesions as evidenced by patient pain rating

**Expected Outcome:** The patient will experience relief as evidenced by a decrease in pain rating to a level that is acceptable to patient.

**Evaluation of Outcome:** Does patient state relief of pain level is acceptable?

**Intervention**
Assess pain using the WHAT’S UP? format. **Rationale** Assessment of the characteristic of the pain assists the nurse in providing appropriate relief measures. **Evaluation** Can patient describe the pain characteristics?

**Intervention**
Recommend pain relief measures appropriate to the type and location of the pain (both alternative measures, such as heat, ice, and change of position, and medication may be offered). **Rationale** Not all types of pain respond well to the same treatment. **Evaluation** Does patient express satisfactory relief of pain? Does patient move and rest without evidence of pain?

**Intervention**
Document results of pain relief measures. **Rationale** Documentation alerts other caregivers about what works and does not work, thus providing more consistent, effective pain relief. **Evaluation** Have you gained sufficient information from patient to document results?

**Intervention**
Instruct patient about self-care for pain and STI treatment at home. **Rationale** Most STIs are treated at home. **Evaluation** Does patient verbalize understanding of self-care measures?

**Nursing Diagnosis:** Risk for Infection, transmission to others, related to lack of knowledge about transmission, symptoms, and treatment

**Expected Outcome:** The patient will verbalize understanding of measures to prevent transmission to others.

**Evaluation of Outcome:** Does patient verbalize understanding of transmission prevention? Does patient practice preventive behaviors?

**Intervention**
Assess patient’s understanding of transmission, symptoms, complications, and treatment of STIs. **Rationale** New instruction should be based on patient’s previous knowledge. **Evaluation** Is patient’s current understanding accurate? What teaching is needed?

**Intervention**
Assess whether patient is engaging in high-risk behaviors. **Rationale** If patient is continuing to engage in high-risk behaviors, the risk for infection of others is high. **Evaluation** Is patient protecting self and others appropriately?

**Intervention**
Use standard precautions and strict aseptic technique for all procedures involving blood and body fluids. **Rationale** The health team, in addition to other patient contacts, must be protected. **Evaluation** Are standard precautions observed?

**Intervention**
Instruct patient in appropriate strategies to reduce risk of infecting others: • Abstinence • Monogamy (if no active infection) • Use of barrier methods and spermicides • Adherence to treatment regimen. **Rationale** These measures may help prevent transmission of infection to others. **Evaluation** Does patient verbalize understanding of methods to prevent transmission and intent to practice them?
**NURSING CARE PLAN for the Patient With Genital Herpes—cont’d**

**Intervention** Teach patient signs and symptoms of STIs to report immediately. **Rationale** Prompt treatment of patient and partners further reduces risk of transmission of infection. **Evaluation** Does patient verbalize understanding of signs and symptoms to report?

**Intervention** Explain importance of follow-up evaluation. **Rationale** Follow-up is essential to affirm that treatment was successful. **Evaluation** Does patient make a follow-up appointment?

**Nursing Diagnosis:** Fear related to diagnosis of an incurable illness and effects on sexual relationships and reproduction as evidenced by patient statement

**Expected Outcomes:** The patient will relate accurate knowledge and control of excessive fear.

**Evaluation of Outcomes:** Does patient relate accurate knowledge? Is fear manageable?

**Intervention** Assess patient’s fears. **Rationale** Fear is a normal response and may be appropriate. **Evaluation** What specifically does the patient fear?

**Intervention** If fear is based on misconceptions, provide factual information. **Rationale** When fear is based on misconceptions, they should be corrected. **Evaluation** Are fears based on factual information?

**Intervention** Allow patient to verbalize feelings. Be empathetic, but do not offer false hope. **Rationale** Sharing fears may help patient gain insight into dealing with them. **Evaluation** Is patient able to verbalize feelings?

**Intervention** Explain all procedures and treatments. **Rationale** Unfamiliar procedures or treatments may contribute to fear. **Evaluation** Does patient understand procedures and treatments?

**Intervention** Help patient identify support systems and coping strategies that have worked in the past. **Rationale** Methods that have worked for patient before are likely to be helpful again. **Evaluation** Does patient have effective coping skills and support systems?

**Nursing Diagnosis:** Readiness for Enhanced Self-Health Management related to lack of knowledge about STIs as evidenced by patient requesting information

**Expected Outcome:** The patient will verbalize realistic and accurate information about disease prevention.

**Evaluation of Outcome:** Does patient relate accurate knowledge and plans for prevention?

**Intervention** Assess the patient’s health beliefs and correct misconceptions. **Rationale** Many myths about sexual activity are sincerely believed by some patients (see Table 44.4). **Evaluation** Does patient have an accurate understanding of STI prevention?

**Intervention** Explain the importance of patients knowing the sexual and lifestyle history of any potential partner before sexual activity has occurred. **Rationale** Having a sexual relationship with someone is the epidemiological equivalent of engaging in sexual activity with all of that person’s previous partners. **Evaluation** Can patient relate a plan to approach this subject with a potential partner?

**Intervention** Provide pamphlets or other materials. (Make sure the patient is able to read.) **Rationale** Written materials can reinforce teaching. **Evaluation** Is patient observed viewing materials offered?

**Intervention** Explain that abstinence or lifelong monogamy of both sexual partners in a relationship is the only sure prevention against STIs. **Rationale** These practices eliminate risk of exposure. **Evaluation** Does patient relate understanding of monogamy?
TABLE 44.4  COMMON MYTHS ABOUT SEXUALLY TRANSMITTED INFECTIONS

</thead>
<tbody>
<tr>
<td>People who have STIs are easily identifiable.</td>
<td>Inspection of the potential partner’s genitals before sexual activity may decrease the risk (if one does not participate in sexual activity with a person who has visible lesions), but:</td>
</tr>
<tr>
<td></td>
<td>• Not all people who are infected have visible symptoms.</td>
</tr>
<tr>
<td></td>
<td>• There is no standard personality or physical profile for people who can be infected with STIs— anyone can be and may be infected.</td>
</tr>
<tr>
<td>Avoiding persons who have a history of engaging in casual sex, IV drug use, homosexual activity, bisexual activity, or a previous sexual relationship with persons who engage in these high-risk practices effectively protects one from infection with STIs.</td>
<td>Avoiding people with these types of history may decrease risk, but:</td>
</tr>
<tr>
<td></td>
<td>• Not everyone is honest when responding to questions about sexual history.</td>
</tr>
<tr>
<td></td>
<td>• Not everyone is aware of their previous partners’ histories or the histories of others with whom their previous partners have had sexual relationships.</td>
</tr>
<tr>
<td></td>
<td>• Asking such questions is difficult and may be avoided until it is too late.</td>
</tr>
</tbody>
</table>

NURSING CARE PLAN for the Patient With Genital Herpes—cont’d

**Intervention** Educate the patient that consumption of alcohol or other psychoactive drugs can reduce inhibitions and may result in unintended sexual encounters, which can transmit STIs. **Rationale** Avoiding or limiting alcohol and other drug consumption when with potential partners may help prevent STI infection from occurring. **Evaluation** Does patient relate a plan to limit the effect of substances on sexual encounters?

**Nursing Diagnosis:** Ineffective Sexuality Pattern related to infection and risk for transmission of infectious organism

**Expected Outcome:** The patient will describe acceptable, alternative sexual practices and safer sex practices.

**Evaluation of Outcome:** Does patient relate safer sex practices?

**Intervention** Provide privacy and be verbally and nonverbally nonjudgmental when allowing patient and patient’s partner to express concerns about sexual practice. **Rationale** Treatment success rates are generally higher when a rapport is established with the health care provider and the partner is included in the decision-making process. **Evaluation** Do the patient and partner express concerns?

**Intervention** When teaching patients, use safer sex terminology. **Rationale** Safer sex practices may decrease the risk of (but not absolutely prevent) transmission of STIs (Table 44.3). Safe sex and STI prevention are misnomers, since no practices provide absolute protection. **Evaluation** Does patient exhibit understanding of the concept of safer sex?

**Intervention** Discuss alternative means of sexual expression, as appropriate. **Rationale** This may allow for intimacy when the desired sexual expression is not recommended, such as during treatment. **Evaluation** Can patient identify some acceptable (to patient) alternative means of sexual expression?

**Intervention** Support realistic expectations about treatment and outcomes. **Rationale** Unrealistic expectations may lead to additional undesired issues related to sexuality pattern. **Evaluation** Does patient have realistic expectations?

For more information on STIs, visit www.cdc.gov/std/healthcomm/fact_sheets.htm and www.ashastd.org.

<tr>
<td>Condoms prevent the spread of all STIs.</td>
<td>Condoms can greatly decrease the risk of STIs, but:</td>
</tr>
<tr>
<td></td>
<td>• Condoms can have tiny channels in the latex or other material that can allow microorganisms to pass through.</td>
</tr>
<tr>
<td></td>
<td>• Condoms can break, slip off, or be applied improperly.</td>
</tr>
<tr>
<td></td>
<td>• Petroleum-based lubricants may weaken latex condoms.</td>
</tr>
<tr>
<td></td>
<td>• Condoms do not provide a barrier for any area other than the penis and most of the vagina or anus. Some STIs may still be transmitted by contact with surrounding uncovered tissues.</td>
</tr>
<tr>
<td>The female condom prevents all transmissions of STIs.</td>
<td>It does cover more surface area, but it may have problems similar to male condoms (see previous entry).</td>
</tr>
<tr>
<td>Manual, oral, and anal stimulation cannot transmit STIs.</td>
<td>Contact of hands to genitals can allow for transmission of microorganisms through breaks in the skin. Oral sex can transmit some STI-causing microorganisms. Anal intercourse is a very high-risk activity for transmission of STIs because anal tissues are easily injured and the gastrointestinal tract can be a reservoir for many microorganisms.</td>
</tr>
<tr>
<td>Nonoxynol-9 spermicide kills all STI germs.</td>
<td>Nonoxynol-9 can reduce the risk of transmission of STIs, but:</td>
</tr>
<tr>
<td></td>
<td>• Nonoxynol-9 is not guaranteed to kill all microorganisms.</td>
</tr>
<tr>
<td>People get AIDS only by homosexual sexual activity or by blood transfusion.</td>
<td>Homosexual activity may result in a higher incidence of transmission of HIV, but:</td>
</tr>
<tr>
<td></td>
<td>• HIV can be transmitted during heterosexual activity.</td>
</tr>
<tr>
<td>A woman cannot transmit HIV to a man.</td>
<td>Gender does not protect a person from being infected with HIV.</td>
</tr>
<tr>
<td>A man cannot transmit HIV to a woman.</td>
<td></td>
</tr>
<tr>
<td>Sexual activity during menstruation is less likely to result in STIs.</td>
<td>Sexual activity during menstruation is more likely to result in transmission of some microorganisms that cause STIs because of the vulnerability of the lining of the uterus caused by sloughing of the outer layers of cells and because blood and cellular debris may serve as a nutritious medium for growth of microorganisms.</td>
</tr>
<tr>
<td>Lesbian sexual activity cannot transmit STIs.</td>
<td>Transmission of microorganisms can occur by contact with mouth, anus, genital tissues, or fomites (inanimate objects, such as vibrators and other sex paraphernalia) that have been contaminated with microorganisms from an infected person—regardless of the original source of the infection.</td>
</tr>
<tr>
<td>Those who have not been infected after sexual activity with several people are naturally immune to STIs.</td>
<td>There is no known natural immunity to STIs. The person may not yet have had contact with someone who has an active STI.</td>
</tr>
</tbody>
</table>
TABLE 44.4  COMMON MYTHS ABOUT SEXUALLY TRANSMITTED INFECTIONS—cont’d

<table>
<thead>
<tr>
<th>Myth</th>
<th>Factual Data</th>
</tr>
</thead>
<tbody>
<tr>
<td>Those who have had an STI and have been cured of it by taking medicine are now immune to that infection.</td>
<td>Infection that has been eradicated by medication does not confer immunity.</td>
</tr>
</tbody>
</table>

Testing of those who suspect they may have contracted an STI and treatment (if possible) may decrease the spread of STIs, but:
- No one test identifies all STIs. Some are identified by examination, and not all infected people show symptoms.
- Some STIs do not show positive test results for long periods yet may be transmitted by the person while the tests are still negative.
- People may be infected with more than one agent at a time, and each must be treated (if possible). One STI may obscure the symptoms of other concurrent STIs, so that one or more types may go unnoticed and untreated or may not be evident until other STIs have been treated.
- There are no known cures for some STIs.

People can be certified free of all STIs by having a blood test and taking a simple medication if an infection is present.

Oral contraceptives are not antibiotics—they provide only some protection against conception.

Use of a barrier method with spermicide along with the oral contraceptive can decrease risk of STIs and pregnancy.

CRITICAL THINKING

Stephanie

As you seat a young woman in an examining room of the clinic where you work, she comments, “I am new to this area, and I’ve heard that there are three guys in this town who have syphilis and are spreading it around. Is that true?”

1. What are some concerns this question might reflect?
2. You find out that Stephanie knows very little about syphilis. List in outline form a teaching plan that includes the information that is important for Stephanie to know about syphilis.

Suggested answers are at the end of the chapter.

SUGGESTED ANSWERS TO CRITICAL THINKING

Mrs. Miller

1. You can educate Mrs. Miller about the possibility of neonatal infections from *C. trachomatis* or *N. gonorrhoeae*, especially of the eyes. Institutional and governmental policies related to treatment should be explained. Care should be taken to explain to Mrs. Miller that treatment is widely used, so as not to make her feel she has a condition she has not been told about.
2. Because the benefits of prophylactic eye treatment of the neonate for *C. trachomatis* and *N. gonorrhoeae* exposure are generally seen as greater than the risks, it is recommended by governmental agencies and supported by most institutional policies to treat all newborns, regardless of known exposure, shortly after birth.

Kerri

1. Explain to Kerri the fact that trichomoniasis is often an STI, but that the organism that causes the infection can be transmitted through infected articles during nonsexual contact, can survive a long time outside the body, and that one can be asymptomatic for many
years following exposure to the organism before an outbreak occurs. Her partner could also have an undiagnosed infection.

2. You don’t want to assume the HCP is wrong. An approach might sound something like, “I noticed in the drug guide that the usual dose is 2 grams, but I see you have written for 4 grams.”

3. Teach Kerri that treatment should be provided to her partner regardless of symptoms. Also, reinfection may occur if both partners are not treated. Teach her how the infection is spread and how to avoid it in the future. She and her partner should use condoms or remain abstinent until treatment is effectively completed. Be sure to tell her that she should abstain from alcohol while on metronidazole and for at least 48 hours following its completion. Patients who drink alcohol while taking it are very likely to vomit.

SUGGESTED ANSWERS TO—cont’d

**Stephanie**

1. Concerns might include (a) a wish to speak with a health care worker, (b) uncertainty about whether patient information will be kept confidential (give assurance that if you knew about anyone with syphilis, it would be your professional responsibility to keep it confidential), (c) fear that she might have become infected through heterosexual contact, (d) a desire to protect herself by avoiding those who have syphilis, and (e) a desire for information about syphilis and its transmission routes.

2. The teaching plan might include information about (a) the spirochete that causes syphilis, (b) signs and symptoms, (c) diagnostic tests, (d) means of transmission, (e) strategies for risk reduction, (f) treatment, (g) research, and (h) rights and responsibilities of those who have the disease.

REVIEW QUESTIONS

1. What signs and symptoms of STIs should nurses assess for in all patients? **Select all that apply.**
   1. Itching
   2. Discharge
   3. Dysuria
   4. Genital ulcers
   5. Genital warts
   6. Rectal pain

2. A young woman is seen at a walk-in clinic and is diagnosed with an STI. She says, “How could I have an STI? I only have sex with my boyfriend. I don’t sleep around!” Which of the following responses by the nurse is best?
   1. “You are right, that should have kept you safe. There just are no guarantees.”
   2. “If your boyfriend is not infected, then it is apparent that you have had sex with someone else.”
   3. “You or your boyfriend could be infected from past sexual encounters. He should also be tested at this time for STIs.”
   4. “Even lifelong monogamy cannot prevent many STIs.”

3. A home care nurse is preparing to change a dressing on a patient who had genital warts removed the previous day. Which intervention should be completed first?
   1. Clean the wounds.
   2. Remove the old dressing.
   3. Assess for drainage.
   4. Administer an analgesic.

4. An older man is admitted to the hospital with mental status changes. As the nurse begins the shift assessment, the patient begins to cry and says his doctor thinks his problems stem from an untreated syphilis infection when he was in the military as a young man. Which response by the nurse is best?
   1. “Why didn’t you have it treated when it occurred?”
   2. “What’s done is done; it’s unfortunate that treatment is too late now.”
   3. “That must be upsetting for you. Do you want to talk about it?”
   4. “Don’t cry; I am sure there is treatment that can help now.”

5. A nurse has completed instruction related to STI risk reduction with a 17-year-old woman. Which statement by the patient indicates that teaching has been effective?
   1. “I should avoid drinking alcohol when I will be in situations with potential sex partners.”
   2. “If I make sure my partners wear condoms, I will be protected from STIs.”
   3. “Use of a barrier method of birth control will prevent infection with an STI.”
   4. “As long as I know my partner well, I am safe.”

Answers can be found in Appendix C.

synovitis (sin-oh-VY-tiss)
vertebrae (VER-teh-bray)

LEARNING OUTCOMES

1. Explain the normal anatomy and function of the musculoskeletal system.
2. Describe the effects of aging on the musculoskeletal system.
3. List subjective data that are collected when caring for a patient with a disorder of the musculoskeletal system.
4. List the objective data that are collected when caring for a patient with a disorder of the musculoskeletal system.
5. List areas included in a neurovascular assessment that relate to the musculoskeletal system.
6. Identify diagnostic tests for musculoskeletal problems.
7. Describe the nursing care provided for patients undergoing diagnostic tests of the musculoskeletal system.
NORMAL MUSCULOSKELETAL SYSTEM ANATOMY AND PHYSIOLOGY

The skeletal and muscular systems can be considered as one system because together they move the body. The skeleton is the framework of the body to which the voluntary muscles are attached. The framework includes the joints, or articulations, between bones. Contraction of a muscle stabilizes or changes the angle of a joint. Movement would not be possible without the proper functioning of the nervous, cardiovascular, and respiratory systems. Voluntary muscles require nerve impulses to contract, a continuous supply of blood provided by the circulatory system, and oxygen provided by the respiratory system.

SKELETAL SYSTEM TISSUES AND THEIR FUNCTIONS

The tissues that make up the skeletal system are primarily bone tissue, articular cartilage, and fibrous connective tissue that forms the ligaments (that connect bone to bone) and other structures within joints. The tissues of the muscular system include skeletal muscle tissue and fibrous connective tissues. The fibrous connective tissue forms tendons (which connect muscle to bone) and fasciae (the strong membranes enclosing individual muscles).

Besides its role in movement, the skeleton has other functions. It protects organs and tissues from mechanical injury. In particular, the brain is protected by the skull, and the heart and lungs are protected by the thoracic cage. Flat and irregular bones as well as the ends of long bones contain red bone marrow, the hematopoietic (blood-forming) tissue. The bones also store excess calcium, which may undergo resorption (bone broken down with minerals including calcium released into blood) for blood calcium homeostasis. Calcium in the blood is needed for blood clotting and for the proper functioning of nerves and muscles.

Although the primary function of the muscular system is to move or stabilize the skeleton, the voluntary muscles collectively contribute significantly to heat production, which maintains normal body temperature. Another important function of the muscular system is to aid in the return of blood from the legs through muscular compression on the leg veins.

Bone Tissue and Bone Growth

Bone tissue is composed of bone cells, called osteocytes, within a strong, nonliving matrix made of calcium salts and the protein collagen. In compact bone, the osteocytes and matrix are in precise, densely structured arrangements called osteons. In spongy bone, the arrangement of cells and matrix is more irregular and sparse, giving the bone a spongy appearance. Compact bone forms the diaphyses (shafts) of the long bones, covers the spongy bone of the epiphyses of long bones, and covers the spongy bone that forms the bulk of short, flat, and irregular bones.

Chapter 45

Musculoskeletal Function and Assessment

Osteoblasts produce bone matrix during growth and replace matrix during normal remodeling or in repair of fractures. Other cells called osteoclasts resorb bone matrix when more calcium is needed in the blood, or during repair when excess bone must be removed as bone changes shape.

The growth of bone from fetal life until final adult height depends on many factors. Proper nutrition (particularly vitamins and minerals) provides the raw material to produce bone matrix, comprising calcium, phosphorus, and protein. Vitamin D is essential for the efficient absorption of calcium and phosphorus in the small intestine. Vitamins A and C are required for the production process of bone matrix. Hormones directly needed for growth include growth hormone (GH) from the anterior pituitary gland, thyroxine from the thyroid gland, and insulin from the pancreas. GH increases mitosis and protein synthesis; thyroxine stimulates osteoblasts and also increases energy production. Insulin is essential for the efficient use of glucose to provide energy. If a child is lacking any of these hormones, growth is slower, and the child may not reach his or her genetic potential for height.

Bone is not a fixed tissue, even when growth in height has ceased. Calcium and phosphate are constantly being removed and replaced (remodeled) to maintain normal blood levels of these minerals. Parathyroid hormone, secreted by the parathyroid glands, increases the removal of calcium and phosphate from bones; the hormone calcitonin from the thyroid gland promotes the retention of calcium in bones.

Structure of the Skeleton

The 206 bones of the human skeleton are in two divisions: the axial and appendicular skeleton. (Fig. 45.1; axial in white, appendicular in turquoise). The axial bones are flat or irregular bones and contain red bone marrow (hematopoietic tissue). Within the appendicular skeleton, the limbs consist of long bones (except the carpals, tarsals, and patellae). All long bones have the same general structure: a central diaphysis, or shaft, with two ends called epiphyses.

Skull

The skull consists of 8 cranial bones and 14 facial bones, and also contains the 3 auditory bones found in each middle ear cavity. All of the joints between the cranial bones and those between most of the facial bones are immovable joints called sutures.

Vertebral Column

The vertebral column (or spinal column) is made of individual bones called vertebrae (Fig. 45.2). Atlas, the first cervical vertebra, articulates with the occipital bone of the skull and forms a pivot joint with the axis, the second cervical vertebra. The thoracic vertebrae articulate with the posterior ends of the ribs. The lumbar vertebrae are the largest and strongest. The sacrum articulates with the os coxae at the sacroiliac joints. The coccyx serves as an attachment point for some muscles of the perineum.

The vertebrae as a unit form a flexible backbone that supports the trunk and head and contains and protects the...
spinal cord. Spinal nerves and vessels exit via intervertebral foramina. Intervertebral discs cushion and permit movement of the column.

**Thoracic Cage**

The thoracic cage consists of 12 pairs of ribs and the sternum. The thoracic cage protects the heart and lungs, as well as upper abdominal organs such as the liver and spleen, from mechanical injury. During breathing, the flexible thoracic cage is pulled upward and outward by the external intercostal muscles to expand the chest cavity and bring about inhalation.

**Synovial Joints**

The primary joints of the appendicular skeleton are summarized in Table 45.1. All freely movable joints (diarthroses) are synovial joints (Fig. 45.3). Many synovial joints also have bursae (small sacs of synovial fluid between the joint and structures that cross over the joint). Bursae lessen wear in areas of friction.

**MUSCLE STRUCTURE AND ARRANGEMENTS**

One muscle can consist of thousands of skeletal muscle cells (fibers), which are specialized for contraction. When a muscle contracts, it shortens and exerts force on a bone. Each muscle fiber receives its own motor nerve ending, and the numbers of fibers that contract depend upon the workload. Muscles are anchored to bones by tendons, which are made of fibrous connective tissue. A muscle usually has at least two tendons, each attached to a different bone. The more stationary muscle attachment is called its origin; the more movable attachment is the insertion. The muscle itself crosses the joint formed by
the two bones to which it is attached, and when the muscle contracts, it pulls on the insertion moving the bone in a particular direction. The muscle causing this particular action is termed the agonist.

There are approximately 700 skeletal muscles in the body (Fig. 45.4). The general type of arrangement is the agonist with opposing antagonists and the cooperative synergists. Without synergism, maintaining balance or having fine motor control for writing or talking would be difficult if not impossible.

**ROLE OF THE NERVOUS SYSTEM**

Skeletal muscles are voluntary: conscious control initiates nerve impulses to cause contraction. Nerve impulses originate in the motor areas of the frontal lobes of the cerebral cortex. The coordination of voluntary movement is a function of the cerebellum. Neurons in the central nervous system (CNS) also act involuntarily to regulate muscle tone, the state of slight contraction usually present in muscles. Healthy muscle tone is important for posture and coordination.

**Neuromuscular Junction**

Each of the fibers in a muscle has its own motor neuron ending. The neuromuscular junction is the termination of the motor neuron at the muscle fiber. The neuron releases the neurotransmitter acetylcholine (Ach), which signals muscle contraction (Fig. 45.5).

1. An action potential travels along the motor neuron, reaching the synaptic end bulb.
2. Acetylcholine is exocytosed (process in which a cell releases a large molecule) from vesicles into the synaptic cleft and bonds with receptors on the motor end plate.
3. An action potential initiates and travels along the sarclemma and into the transverse tubules, transferring to the sarcoplasmic reticulum.
4. Calcium ions released from the sarcoplasmic reticulum bond to troponin of the thin filament, exposing bonding sites on actin for myosin heads. Myosin of the thick filament attaches and pulls the thin filament, shortening the sarcomeres and thus the muscle fiber.

If a muscle has little work to do, few of its many muscle fibers contract; but if the muscle has more work to do, more of its muscle fibers contract.

**AGING AND THE MUSCULOSKELETAL SYSTEM**

The amount of calcium in bones depends on several factors (Fig. 45.6). Good nutrition is certainly one factor, but age is another, especially for women. One function of estrogen (or testosterone) is the maintenance of a strong bone matrix. For women after menopause, bone matrix loses more calcium than is replaced. Osteoporosis may result in bone fractures. The loss can be offset by weight-bearing physical exercise, which stimulates bone matrix deposition, increasing bone density.
UNIT TWELVE  Understanding the Musculoskeletal System

Weight-bearing joints are also subject to damage after many years. Often the articular cartilage wears down and becomes rough, leading to pain and stiffness.

Muscle strength declines with age as protein synthesis decreases. Such loss of strength need not be exaggerated because aging muscles also benefit from regular exercise. Furthermore, maintenance of muscle strength reduces falls and accidents (see “Evidence-Based Practice”).

**EVIDENCE-BASED PRACTICE**

**Clinical Question**
What are the risk factors of falls in patients with cognitive impairment?

**Evidence**
An observational study of residential care patients older than 60 years, with cognitive impairment, who had a life expectancy of at least 6 months and were not bed bound or recently discharged from the hospital revealed the following risk factors: medications (especially antidepressants), functional impairment, poor gait and balance, impulsivity, dementia, attention and orientation impairment, and poor memory. Factors that especially put residents at risk were poor attention and orientation, increased postural sway with eyes closed, anxiety, and use of antidepressants.

**Implications for Nursing Practice**
Attention to fall risk factors can guide care planning in high-risk populations of dementia patients.

**REFERENCE**

**NURSING ASSESSMENT OF THE MUSCULOSKELETAL SYSTEM**

Initial assessment of the patient begins with a history that includes the effects the condition is having on the patient’s life. It then proceeds to a physical and psychosocial assessment (Table 45.2). Frequent neurovascular assessments may be

needed if there is a risk of circulation impairment, such as might happen if the patient has a fracture or has had musculoskeletal surgery (Table 45.3).

**Health History**

The patient’s history should include the following:

- For an injury, how and when it happened
- Risk factors for musculoskeletal problems and family history of musculoskeletal problems (to detect hereditary factors)
- Diet history (including whether calcium and vitamin D intake are adequate to ensure proper bone and muscle maintenance and repair)
- Occupation and activities, including sports and other physical activities
- Information specific to the patient’s musculoskeletal problems.

Patients with musculoskeletal problems frequently report pain or related stiffness and tenderness as a major concern. The pain may be acute or chronic and may limit the patient

</tr>
</tbody>
</table>
in everyday life. Assessment includes previous diagnoses, pain severity, medications, treatments, and procedures the patient uses to alleviate the pain. The WHAT’S UP? model can be used to assess the patient’s pain (see Chapter 1).

**Physical Examination**

Three areas of musculoskeletal data collection are important: inspection, palpation, and range of motion (ROM). If the patient can walk, inspect posture and gait, noting poor posture or alterations in movement, such as limping. Note the use of mobility aids, such as a cane or walker. Document other gross deformities, such as unequal limbs, malalignment, or contractures. Spinal deformities are especially significant because they can compromise breathing and balance. Inspect the joints and muscles of the arms, hands, legs, and feet for deformity, redness, swelling, or crepitation (grating sound as joint or bone moves). Also note the patient’s general nutritional status (e.g., normal, obese, emaciated).

After inspection, gently palpate for warmth and tenderness in the areas of swelling, and areas where the patient reported pain (being careful to minimize the pain this may cause). For example, reddened joints should be palpated for synovitis (swollen synovial tissue within the joint) or the presence of bony nodes. In some cases, joints and muscles may seem healthy but are tender when palpated.

Next, observe joint mobility. Stabilize the body area proximal to the joint being moved. Observe the patient’s ROM for performing independent activities of daily living (ADLs). Pay particular attention to the hands and observe movement in finger joints. For a quick and easy check of ROM in the hands, ask the patient to touch each finger, one by one, to the thumb (known as opposition) and then to make a fist. Also note the size, shape, strength, and tone of muscles. Evaluate bilateral muscle strength by asking the patient to grip your hands. This enables you to feel the strength and equality. Pushing an extremity against your hand provides a general indication of muscle strength. More specific evaluation is performed by a physical therapist (PT) or an occupational therapist (OT). Using a scale of 0 to 5 (0 paralysis and 5 moving a muscle against resistance), the PT or OT measures the strength of each muscle group and rates it as a fraction. For example, 5/5 means that the patient reached 5 out of a possible 5 on the muscle strength scale.

**Psychosocial Data Collection**

Deformities resulting from arthritis or other musculoskeletal disorders can affect a patient’s body image and self-concept and result in social withdrawal (see Chapter 46). Chronic pain may keep the patient from working or socializing. Data collection should include questions related to the psychological effects of the musculoskeletal disorder.

</table>
Patients may experience psychological stress from the withdrawal from friends and family, pain, and loss of income. Determine the patient’s ability to cope, asking what coping strategies have been used in the past for other life stressors and support systems for the patient. As needed, consult the appropriate member of the health care team (social work, clergy, support groups) to ensure that the patient’s psychosocial needs are being met.

**CRITICAL THINKING**

**Mrs. O’Donnell**

- Mrs. O’Donnell, age 80, is brought to the emergency department with a fractured left hip. She is positioned for comfort while you collect data.

1. What subjective and objective data should you look for in Mrs. O’Donnell’s history?
2. What should be assessed in Mrs. O’Donnell’s physical examination?

Suggested answers are at the end of the chapter.

**DIAGNOSTIC TESTS FOR THE MUSCULOSKELETAL SYSTEM**

Diagnosis of musculoskeletal problems is assisted by laboratory tests and diagnostic imaging (Table 45.4 and Table 45.5). Specific tests for connective tissue diseases are described in Chapter 46.

**Laboratory Tests**

**Calcium and Phosphorus**

Bone disorders commonly cause changes in calcium and phosphorus (or phosphate) levels. In a healthy person, calcium and phosphorus have an inverse relationship. This means that when serum calcium increases, serum phosphorus decreases, and vice versa. Some disorders, however, cause an increase in both values or a decrease in both values. Calcium and phosphorus levels are regulated by calcitonin from the thyroid gland and parathyroid hormone from the parathyroid glands. When these glands are not functioning properly, alterations in calcium and phosphorus levels can occur.

Serum calcium tends to decrease in patients with osteoporosis or in people who consume inadequate amounts of calcium.

</tbody>
</table>
in their diets. Serum calcium levels increase in patients with bone cancer, particularly those with metastatic disease.

**Alkaline Phosphatase**

Alkaline phosphatase (ALP) is an enzyme that increases when bone or liver tissue is damaged. In metabolic bone diseases and bone cancer, ALP increases to reflect osteoblast (bone-forming cell) activity.

**Myoglobin**

Myoglobin is a protein found in striated (skeletal or cardiac) muscle. It is what causes the red color of muscle. When skeletal or cardiac muscle is damaged, myoglobin levels rise in the blood.

**Muscle Enzymes**

When muscle tissue is damaged, a number of serum enzymes are released into the bloodstream, including skeletal muscle creatine kinase (CK-MM [CK3]), aldolase (ALD), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH).

**Rhabdomyolysis.** Rhabdomyolysis is a very serious and potentially fatal condition associated with muscle destruction due to an injury (such as crush syndrome), high fever, convulsions, or prolonged muscle compression. The patient’s creatine kinase (CK) levels can be five times greater than normal. If the patient has muscle destruction, look for elevated CK, myoglobin, and serum potassium levels to monitor for rhabdomyolysis. Also observe for dark urine, muscle weakness, and myalgia (muscle pain). The goal of treatment is to restore normal fluid and electrolyte balance.

**Uric Acid**

Uric acid is normally found in blood. When uric acid levels rise in the serum, a condition called gout can occur (Chapter 46).
Other Diagnostic Tests

X-Rays
An x-ray examination can determine bone density, texture, changes in alignment and bone relationship, erosion, swelling, and intactness. In addition, x-ray examinations can be useful in identifying certain soft tissue damage (e.g., ligaments and tendons) because of alterations in bone position and spacing.

Computed Tomography
Tomograms can show a particular slice of bone or soft tissue, such as ligaments and tendons. Computed tomography (CT) is especially helpful for diagnosing problems of the joints or vertebral column (Fig. 45.7). It may be used with or without contrast medium, which is given orally or intravenously (IV).

Bone Density Screening
A bone density test measures both bone strength and weight-bearing abilities. A special x-ray process, dual-energy x-ray absorptiometry (DEXA), measures bone density. It is used to diagnose osteoporosis (Chapter 46).

Arthrography
An x-ray examination of any synovial joint can be performed for patients with suspected joint trauma. The most common joints tested are the knee and shoulder.

Myelogram
During a myelogram, a contrast medium is injected into the subarachnoid space so that the spine and spinal cord can be visualized. Inform patients that they may be positioned head down for a short period to allow the contrast medium to flow up to the level of the neck. This test is usually reserved for those patients unable to have a CT or magnetic resonance imaging (MRI) scan or for complicated spinal surgery revisions.

Magnetic Resonance Imaging
MRI, with or without contrast medium, is a commonly performed test to diagnose musculoskeletal problems, especially those involving soft tissue (“Patient Perspective”). MRI is more accurate than CT for diagnosing many problems of the vertebral column (Fig. 45.8). If the patient has had previous spinal surgery, a contrast medium is used (see Chapter 36 for contrast-induced nephropathy).

Patient Perspective
Emily: Undergoing an MRI
After a traumatic injury, I had an MRI and was instructed on the procedure. I had seen MRI scanners on TV, but didn’t know much about them. I knew I had to lie still and not move. I knew if I opened my eyes, I would start getting scared, so I kept them closed. I did take a peek, and saw a part of the machine just inches from my face. I closed my eyes, and repeated in my head, “Inhale, exhale, relax. Inhale, exhale, relax,” a mantra I had learned in yoga class. I could feel myself going in and out of consciousness, but when I was conscious I repeated my mantra, the only thing that helped me hang on to reality. I didn’t feel any pain, so I thought I was OK. Before I knew it, the test was over and I felt relieved. My personal coping techniques really helped me through the MRI so that I could complete the test. Providing information to patients on what to expect during the test, as well as coping methods to use, can help them successfully complete an MRI.

BE SAFE!
Check with the facility where the MRI will take place for all contraindications for metal implants within a person’s body to prevent injury to the patient.

Nuclear Medicine Scans
Several tests are performed using radioactive material, which is not harmful to the patient, to help visualize bone and other tissues. A bone scan allows visualization of the entire skeleton. The patient is injected with a radioisotope 2 to 3 hours before the scan. The radioisotope is attracted to bone and therefore travels to bone tissue. If the bone scan is ordered to assess for bone infection (osteomyelitis), a picture will be taken immediately after the first injection. Then a second series is done 2 to 3 hours later, once the radioisotope has collected in the bone.
For an accurate test, the patient must be able to lie still for up to 90 minutes during scanning. Patients who are older adults, restless, agitated, or in pain may therefore find this test uncomfortable. Sedatives or analgesics may have to be administered before or during the procedure. Patients need to be instructed to remove all jewelry before testing.

The health care provider (HCP) looks for “hot spots” on the test results. Hot spots are created because increased circulation occurs in abnormal bone areas, resulting in increased amounts of the radioactive substance being transported to the abnormal area by the circulation. These hot spots indicate bone disease.

**Gallium/Thallium Scans**

A gallium or thallium scan is similar to a bone scan but is more specific and sensitive as a diagnostic test. Gallium concentrates in areas of tumors, inflammation, and infections. Traditionally used for heart problems, thallium is now used for evaluation of bone cancers. Thallium is best for detecting osteosarcoma.

**Arthroscopy**

An arthroscopy allows the surgeon to directly visualize a joint. The knee and shoulder are the joints most often evaluated. Because arthroscopy is an invasive procedure performed under local or light general anesthesia, the patient is treated as a surgical candidate in a same-day surgery setting.

The surgeon makes several small incisions and distends the joint with injected saline. The scope is inserted and the joint is visualized from different angles. The joint is moved through range of motion, so tears, defects, or other soft tissue damage can be assessed and/or repaired through the scope using special instrumentation. Depending on the extent of the procedure, a bulky or small dressing wrapped with an elastic bandage may be applied.

The perianesthesia care nurse monitors the neurovascular status of the surgical limb frequently (see Table 45.3). If the patient had a diagnostic arthroscopy and no surgical repair, the perianesthesia care nurse encourages the patient to exercise the leg, including straight-leg raises. A mild analgesic usually relieves pain, and the patient returns to regular activities in 24 to 48 hours. If a surgical repair was performed, the patient may have activity restriction and need a stronger analgesic.

Although complications are not common, teach the patient the signs to report to the surgeon for the following:

- Thrombophlebitis (blood clot and vein inflammation)
- Infection (fever or warmth, pain, redness, swelling at surgical site)
- Increased joint pain.

If a repair was done during the surgery, the patient is seen by the surgeon in 1 week to check for complications and progress. The patient may need crutches for the first week to limit weight bearing, depending on the surgical procedure performed. Physical or occupational therapy may be ordered (see “Home Health Hints”).

---

**Home Health Hints**

- When visiting a patient at home, the nurse needs to determine if the patient is homebound. Patients are considered homebound if:
  1. they are bedbound or require maximum assistance to ambulate while using a walker or to transfer,
  2. they can ambulate with only moderate assistance while using a cane to negotiate uneven surfaces, or
  3. they can leave home only for periods of relatively short duration or when in need of medical treatment.
- If it is determined that the patient is not homebound, then services such as physical and occupational therapy can be performed in an outpatient setting.
- When testing strength, extend two or three fingers and ask the patient to squeeze the fingers. Deficits in arm strength can be easily detected using this simple method.
- Observe patients moving around a room or bed. If they are clumsy or have involuntary movement, make efforts during that visit and later visits to protect them from potential injury. Research has shown that pain or fear of falling may prevent a patient from moving and functioning to maximum potential.
- Use sand or cat box filler on icy steps to increase traction, preventing slips and falls.

---

**Word Building**

**arthroscopy**:
arthro—joint + scopy—to examine
Bone or Muscle Biopsy

Bone or muscle tissue can be surgically extracted for microscopic examination to confirm cancer, infection (bone biopsy), inflammation, or damage (muscle biopsy). Muscle can also be biopsied to diagnose malignant hyperthermia, a genetic disorder (see Chapter 12). Two techniques are used to retrieve muscle tissue: a needle (closed) biopsy or an incisional (open) biopsy.

A closed biopsy can be performed in the patient’s room or special procedures area. After local or general anesthesia, the physician inserts a long needle into the tissue for extraction of a sample.

The open biopsy is performed in the operating suite under general anesthesia. A small incision is made and a section of bone or muscle is removed. A sterile pressure dressing is applied because bone is highly vascular.

The nurse inspects the biopsy site for bleeding, swelling, and hematoma formation. Increased pain that is unresponsive to analgesic medication may indicate bleeding in the soft tissue. Vital signs and neurovascular assessments are monitored (see Table 45.3).

**Ultrasonography**

Sound waves are used to detect osteomyelitis (bone infection), soft tissue disorders, traumatic joint injuries, and surgical hardware placement.

**Arthrocentesis**

Arthrocentesis is a diagnostic or therapeutic procedure in which synovial fluid is aspirated from a joint for analysis or to relieve pressure (pain) from effusion. This fluid buildup often occurs secondary to an inflammatory process such as bursitis. Analysis of the synovial fluid can also aid in the diagnosis of noninflammatory conditions, septic arthritis, crystal detection, and hemarthrosis (blood in the joint cavity). In addition, the removal of fluid will decrease pain and improve mobility.

Using aseptic technique, the physician provides local anesthetic and then uses a needle to aspirate the contents of the joint space. The fluid can then be sent to the lab to evaluate for infection and/or inflammation. If required, the physician will also instill medications such as a corticosteroid, an anti-inflammatory, or an antibiotic. The site is covered with a sterile dressing to prevent infection.

Nursing considerations following the test include monitoring the injection site for increased bruising, bleeding, redness, and warmth.

**Nerve Conduction Studies**

Electromyography (EMG) measures a muscle’s electrical impulses. This aids in the diagnosis of muscle diseases or nerve damage, which may follow a traumatic injury. An indication of nerve damage is limited return of muscle function following injury resolution. Inform the patient what will occur, and instruct the patient not to apply lotions before the test and to remove all jewelry. Occasionally, slight discomfort and bruising occurs at the site where the study occurred. Warm compresses or mild analgesics can be offered for pain relief (see Table 45.5).

---

**CRITICAL THINKING**

**Mrs. Gardenio**

- Mrs. Gardenio, 84 years old, fell when using a step-stool in her home. She was taken to the hospital, where it was determined that she had a femoral neck fracture of her left hip.

1. What data should you obtain from Mrs. Gardenio?
2. What possible condition may be the cause of her fracture?
3. What tests may be performed to identify the condition creating her problem?
4. Mrs. Gardenio is to receive morphine 4 mg by intramuscular injection now. You have available morphine 5 mg/mL. How many milliliters will you give?

Suggested answers are at the end of the chapter.

---

**SUGGESTED ANSWERS TO**

**CRITICAL THINKING**

**Mrs. O’Donnell**

1. Determine if Mrs. O’Donnell has any allergies, how and when the injury occurred, if she has had any previous surgeries, what medications she takes, her medical history, and any past problems with anesthesia (in Mrs. O’Donnell or her family).
2. Inspect her left leg in comparison with her right leg, including limb length, deformity, pain, loss of range of motion, edema, and ecchymosis. Perform neurovascular checks, including movement, sensation (numbness/tingling), presence of pulses, skin temperature, color, and capillary refill.

---

**Mrs. Gardenio**

1. Assess Mrs. Gardenio’s age, her diet (does she have a low-calcium or vitamin D-deficient diet?), what she was doing at the time of the break, whether anything like this has happened before, whether anything similar has happened to any of her relatives, her pain level, when she ate last, her medications, her medical history, whether she smokes, and whether she has any allergies.
2. Mrs. Gardenio may have osteoporosis that has resulted in a pathological fracture from decreased bone density. This is common in postmenopausal women.

Continued
SUGGESTED ANSWERS TO—cont’d

3. X-ray examinations, bone scans, bone density tests, and laboratory tests such as serum calcium, phosphorus, acid phosphatase, thyroid, and vitamin D levels are tests that might be performed.

4. Unit analysis method:
   \[
   \frac{4 \text{ mg}}{1 \text{ mL}} = \frac{4 \text{ mL}}{5} = 0.8 \text{ mL}
   \]

REVIEW QUESTIONS

1. The nurse is assigned to care for a patient who has been diagnosed with a musculoskeletal disease that causes decreased bone density. Which data collection questions are most appropriate by the nurse? Select all that apply.
   1. “Do you have any broken bones?”
   2. “Has your doctor informed you not to exercise so you will not break a bone?”
   3. “What forms of physical activity are you able to participate in?”
   4. “Do any of your spouse’s relatives have problems with their bones?”
   5. “Do you exercise regularly?”
   6. “What is typically included in your daily diet?”

2. The nurse is caring for a patient with a fractured left leg. Which of the following findings during a neurovascular assessment of the lower extremities would the nurse recognize as a priority to report to the health care provider?
   1. Strong bilateral left leg post tibial pulse
   2. Right foot capillary refill less than 2 seconds
   3. Bilateral dorsal flexion
   4. Pallor of the left leg

3. A patient is scheduled for an MRI of the pelvis. Which of the following actions would the nurse take if during data collection it was revealed that the patient had had a previous surgery for heart problems?
   1. Ask if there is any metal in the patient’s body.
   2. Obtain an order for a chest x-ray
   3. Cancel the MRI.
   4. Inform the physician.

4. The nurse is caring for a patient who has undergone an arthroscopy. Two hours after the procedure, the patient’s pedal pulses are diminished compared with the previous assessment. What action should the nurse take?
   1. Take vital signs.
   2. Notify the surgeon.
   3. Perform neurovascular assessment in 30 minutes.
   4. Change the dressing and rewrap the elastic wrap.

5. The nurse is caring for a patient who is undergoing an arthroscopy of the knee with ligament repair. Which of the following would be included in nursing preoperative care for the patient the morning of surgery? Select all that apply.
   1. A soft breakfast
   2. No food after midnight
   3. Explaining the surgical procedure
   4. Explaining the anesthetic agents
   5. Reinforcing how to perform coughing and deep-breathing exercises
   6. Teaching the patient to perform straight-leg raises

Answers can be found in Appendix C.

Nursing Care of Patients With Musculoskeletal and Connective Tissue Disorders

SHARON GORDON

LEARNING OUTCOMES

1. Explain the pathophysiology, signs and symptoms, and complications of fractures.
2. Plan nursing interventions for a patient in a cast, traction, or external fixation.
3. Describe the causes and prevention of osteomyelitis.
4. Plan nursing care for osteomyelitis.
5. Describe risk factors, pathophysiology, treatment, and nursing care for osteoporosis.
6. Describe pathophysiology, signs and symptoms, treatment, and nursing care for Paget’s disease.
7. Describe the pathophysiology, treatment, and nursing care for gout.
8. Compare the care for osteoarthritis and rheumatoid arthritis.
11. Explain the patient education that would be included for a patient with a lower extremity amputation and prosthesis.

synovitis (sin-oh-VYE-tiss)
A variety of injuries and diseases can affect bone, soft tissue, or both and are discussed here.

**Strains**

A strain is a soft tissue injury that occurs when a muscle or tendon is excessively stretched. Causes of strains include falls, excessive exercise, and lifting heavy items. A mild strain causes minimal inflammation; swelling and tenderness are present. A moderate strain involves partial tearing of the muscle or tendon fibers. Pain and inability to move the affected body part result. The most severe strain occurs when a muscle or tendon is ruptured, with separation of muscle from muscle, tendon from muscle, or tendon from bone. Severe pain and disability result from this injury.

**RICE** is an acronym for Rest, Ice, Compression, and Elevation, which is the therapy for strain injuries. Immediately after a strain, the injured area should be rested to protect it. Ice should be applied to decrease pain, swelling, and inflammation. Applying an elastic bandage for compression and elevating the affected area (if appropriate) provide support and minimize swelling. After inflammation subsides, heat application (15–30 minutes for four times a day) brings increased blood flow to the injured area for healing. Activity is limited until the soft tissue heals, and nonsteroidal anti-inflammatory drugs (NSAIDs) are prescribed. Muscle relaxants may also be used. Excercise may begin as early as 2 to 5 days after the injury depending on the severity of the injury; in some cases, it may take 1 to 3 weeks of immobility before exercise can begin. For more severe strains, ambulatory surgery to repair the tear or rupture may be needed.

**Sprains**

A sprain is excessive stretching of ligaments from twisting movements during a sports activity, exercise, or fall. A mild sprain involves tearing of a few ligament fibers that causes tenderness. RICE and NSAIDs are used for severe days until swelling and pain diminish. In a moderate sprain, more fibers are torn, but the stability of the joint is not affected. Moderate sprains may need immobilization with a brace or cast. A moderate sprain is uncomfortable, especially with activity. A severe sprain causes instability of the joint and usually requires surgical intervention for tissue repair or grafting. Pain and inflammation restrict mobility.

**Dislocations**

A dislocation is a common injury in which the ends of the bones are forced from their normal position. This is usually caused by trauma as in falls or contact sports or by a disease such as rheumatoid arthritis. Any joint, large or small, may become dislocated. Severe pain along with loss of range of motion (ROM) of the joint and joint deformity occurs. Immediate medical treatment is required to preserve function. Splint the extremity as it is found, apply ice, and seek help. Do not mo ve the extremity because blood vessels, muscles, and nerves could be damaged.

**Bursitis**

Bursae (fluid-filled sacs) cushion tendons during movement to prevent friction between the bone and tendon. Seveal joints have bursae (shoulder, elbow, hip, knee, ankle, heel). Inflammation of a bursa, called bursitis, occurs from arthritis, gout, repetitive movement, or sleeping on one’s side, which compresses the shoulder bursa. Prevention is key because bursitis may become harder to cure over time. To protect the bursae and prevent compression, teach patients to stretch and strengthen muscles, move frequently, avoid repetitive movements for long periods, use cushioned seats, and avoid leaning on the elbows.

Symptoms of bursitis include achy pain, stiffness, or burning pain over the joint area that worsens with activity. Usually pain decreases in about a week. The condition can become chronic if it lasts more than 6 months. Treatment includes resting the joint, application of ice 20 minutes several times per day until joint warmth is gone, then switching to heat, elevating the joint, ultrasound, massage, NSAIDs, or physical therapy.

**Rotator Cuff Injury**

Short tendons that are connected to muscles around the shoulder form the rotator cuff. The cuff covers the top, front, and back of the shoulder. Muscle contraction causes these tendons to tighten and move or rotate the shoulder. Various cuff injuries can occur. With chronic impingement syndrome, the top tendon of the cuff (supraspinatus tendon) and bursae become impinged in the narrow space under the acromion bone. This causes inflammation when the arm is repeatedly moved forward, and pain results. Over time the tendon can tear from the bone.

Symptoms of rotator cuff injury include shoulder aching, increased pain with lifting the arm, pain that is greater at night, weakness, and sometimes limited ROM. Magnetic resonance imaging (MRI) diagnoses the injury. For minor injury, resting the shoulder, ice, NSAIDs, and physical therapy are recommended. For a severe injury, arthroscopic and/or small-incision surgery relieves the impingement or repairs the tear. A sling or special brace is worn after surgery. Physical therapy is ordered for rehabilitation.

**WORD • BUILDING**

* arthritis: arth(on)—joint + itis—inflammation
Carpal Tunnel Syndrome

Pathophysiology
Carpal tunnel syndrome results in the compression of the median nerve within the carpal tunnel when there is swelling in the tunnel. The swelling can result from edema, trauma, rheumatoid arthritis, or repetitive hand movements (repetitive motion injury) used in some occupations such as typing or factory work.

Signs and Symptoms
Carpal tunnel syndrome usually results in slow-onset finger, hand, and arm pain and numbness. Painful tingling and paresthesia may also be present. Eventually, fine motor deficits and then muscle weakness may develop.

Diagnostic Tests
Diagnosis is based on signs and symptoms and patient history. A positive Phalen’s test (numbness with wrist flexion) indicates carpal tunnel syndrome. Electromyography is used to detect nerve abnormalities.

Therapeutic Measures
Treatment aims to relieve the inflammation and rest the wrist. A splint can be ordered for the patient to wear. Anti-inflammatories such as aspirin and NSAIDs or cortisone injection into the tunnel are used to reduce inflammation and pain.

For some patients, endoscopic or open incision surgery can be needed. The median nerve is released from compression during the surgery, thus correcting the problem of the nerve and the surrounding area becoming inflamed. Physiotherapy helps in the recovery of function.

Nursing Care
Educate the patient on methods to prevent carpal tunnel syndrome, such as frequent short breaks during the workday, alternating nonrepetitive tasks with repetitive movements throughout the day, and using ergonomically appropriate devices to minimize the pressure placed in the area of the wrist.

Manage pain as ordered. After surgery, elevate the patient’s hand and instruct the patient on use of a splint as ordered for up to 2 weeks. Lifting is restricted for several weeks. Teach the patient to report signs and symptoms of neurovascular compromise, such as numbness and tingling, coolness, lack of pulse, pale skin or nailbeds, or limited movement. The patient may need family assistance with activities of daily living (ADLs).

Fractures
A fracture is a break in a bone that can be minor and treated on an ambulatory basis or complex with surgical intervention and rehabilitation.

Pathophysiology
Bone is a dynamic, changing tissue. When it is broken, the body immediately begins to repair the injury (Fig. 46.1). For an adult, within 48 to 72 hours after the injury, a hematoma (blood clot) forms at the fracture site because bone has a rich blood supply. Various cells that begin the healing process are attracted to the damaged bone. In about a week or so, a nonbony union called

FIGURE 46.1 Fracture healing phases.
a callus develops and can be seen on x-ray examination. As healing continues, osteoclasts (bone-destroying cells) resorb any necrotic bone, and osteoblasts (bone-building cells) make new bone as a replacement. This process is referred to as bone remodeling. Young, healthy adult bone completely heals in about 6 weeks; however, it can take up to a year before the whole process of remodeling is complete. An older person takes longer to heal.

Adequate nutrition that includes vitamins, minerals, and protein is essential to heal fractures and keep the musculoskeletal system healthy (see Chapter 45).

**Etiology and Types**

The major reason for a fracture is trauma from a fall, an accident (usually motor vehicle), or a crushing injury. Bone disease (such as osteoporosis and metastatic bone cancer), malnutrition, and regular drinking of carbonated beverages with added phosphoric acid (which may interfere with calcium absorption) can lead to fractures. Side effects from medications can cause a decrease in bone density, resulting in fracture. When fractures result from disease, they are referred to as pathological fractures. Hip fracture is a commonly occurring fracture in middle-aged and older women who have osteoporosis (irreversible bone loss).

In a complete fracture, the bone is broken into two separate pieces. Complete fractures have the potential to be life-threatening because sharp bone fragments can sever blood vessels and nerves. In an incomplete fracture, the bone does not divide into two pieces. With a displaced fracture, the bone sections are out of alignment. In a closed fracture, the bone does not disrupt the skin. In an open fracture, the bone breaks the skin. Open fractures are more likely to become infected than closed fractures. Fractures can be described by the way the bone breaks (spiral or oblique; Fig. 46.2). There are many types of fractures: avulsion, comminuted, impacted, greenstick, interarticular, displaced, pathological (also called neoplastic), spiral, longitudinal, oblique, stress, transverse, and depressed (Table 46.1).
Signs and Symptoms

This section focuses on fractures of upper and lower extremities. If the patient sustains a hairline (microscopic) fracture, the signs and symptoms are not readily observable. The patient may report tenderness over the site of the injury or more severe pain when moving the affected part of the body. The patient with a hip fracture usually experiences pain either in the groin area (the hip is a deep joint) or at the back of the knee (referred pain). If the fracture is complete, the limb is often shortened because of contraction of the muscles pulling on the bone sections.

In addition to pain, patients with more complex fractures experience limb rotation or deformity and shortening of the limb (if a limb bone is broken). ROM is decreased. If the affected part is moved, a continuous grating sound (crepitation) caused by bone fragments rubbing on each other may be heard. The extremity should not be moved (try and reposition the bone alignment) if crepitation is present.

Inspect the skin for intactness. A patient with a closed fracture may have ecchymosis (bruising) over the fractured bone from bleeding into the soft underlying tissue. Ecchymosis may not develop for several days after the injury. Swelling may also be present and can impair blood flow, causing marked neurovascular compromise. In an open fracture, one or more bone ends pierce the skin, causing a wound, thus increasing the possibility of infection.

Diagnostic Tests

An x-ray examination can visualize bone fractures, showing bone malalignment or disruption. Computed tomography (CT) detects fractures of complex areas, such as the hip and pelvis. MRI determines the extent of associated soft tissue damage.

For patients with moderate to severe bleeding, a hemoglobin and hematocrit level is obtained. If soft tissue damage is extensive, the erythrocyte sedimentation rate (ESR) usually is elevated, indicating the expected inflammatory response. The health care provider (HCP) might order a serum calcium level to determine baseline values because bone repair requires a sufficient amount of calcium and other minerals.

Emergency Treatment

A patient with a suspected fracture often has injuries elsewhere in the body. Observe the patient for respiratory distress, bleeding, and head or spine injury. If any of these problems occurs, emergency treatment is provided before concern is given to extremity or other fractures to prevent possible life-threatening complications. Box 46-1 describes emergency interventions for the patient with an extremity fracture.

Fracture Management

The goals of fracture management are reduction, or realignment, of bone ends; immobilization of the fractured bone (with bandages, splints, casts, traction, or fixation device); preservation or restoration of surrounding soft tissue structures such as vessels, tendons, ligaments and muscles; prevention of deformity or further injury; preservation or restoration of function; promotion of early healing; and pain relief.

CLOSED REDUCTION. Closed reduction is the most common treatment for simple fractures. While manually pulling on the bone (limb), the HCP manipulates the bone ends into realignment.

### TABLE 46.1 TYPES OF FRACTURES

<table>
<thead>
<tr>
<th>Fracture Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Avulsion</td>
<td>Piece of bone is torn away from the main bone while still attached to a ligament or tendon.</td>
</tr>
<tr>
<td>Comminuted</td>
<td>Bone splintered or shattered into numerous fragments. Often occurs in crushing injuries.</td>
</tr>
<tr>
<td>Impacted</td>
<td>Bone is forcibly pushed together, resulting in bone being pushed into bone.</td>
</tr>
<tr>
<td>Greenstick</td>
<td>Bone is bent and fractures on the outer arc of the bend. Often seen in children.</td>
</tr>
<tr>
<td>Interarticular</td>
<td>Fracture involves bones within a joint.</td>
</tr>
<tr>
<td>Displaced</td>
<td>Bone pieces are out of normal alignment. One or more pieces may be out of alignment.</td>
</tr>
<tr>
<td>Pathological (also called neoplastic)</td>
<td>Caused when bone is weakened either by pressure from a tumor or an actual tumor within the bone.</td>
</tr>
<tr>
<td>Spiral</td>
<td>Fracture curves around the shaft of the bone.</td>
</tr>
<tr>
<td>Longitudinal</td>
<td>Fracture occurs along the length of the bone.</td>
</tr>
<tr>
<td>Oblique</td>
<td>Fracture occurs diagonally or at an oblique angle across the bone.</td>
</tr>
<tr>
<td>Stress</td>
<td>Results in the bone being fractured across one cortex. This is an incomplete fracture.</td>
</tr>
<tr>
<td>Transverse</td>
<td>Bone fractured horizontally.</td>
</tr>
<tr>
<td>Depressed</td>
<td>Bone pushed inward. Often seen with skull and facial fractures.</td>
</tr>
</tbody>
</table>
Analgesia and/or conscious sedation is given before the procedure. An x-ray is done to confirm that the bone ends are aligned before the area is immobilized by a cast or splint.

BANDAGES AND SPLINTS. For some areas of the body, such as the clavicle or wrist, an elastic or muslin bandage or a splint may be used to immobilize the bone during the healing phase. Splints can be used when the fracture has some associated soft tissue damage that needs care or if there is an expectation of swelling. It is important for the splint to be well padded, thereby preventing skin breakdown or unnecessary pressure. Perform neurovascular assessments hourly (or as ordered) to monitor adequate blood flow to the area until the concern for swelling has passed, then typically every 2 to 4 hours (see Chapter 45).

CASTS. Casts provide a strong support for fractured bones, thereby aiding in early mobility and decreased pain. They are also used to correct deformities and to support weak joints while restricting movement. The type of cast used depends on the reason the cast is applied. For more extensive fractures or for weight-bearing areas, a rigid and durable cast is used for immobilization. When bone healing is complete, the cast is removed.

Several types of materials are used for casts, including the traditional plaster of Paris (anhydrous calcium sulfate) and a variety of synthetic products such as fiberglass. Plaster is used for large casts and for weight-bearing areas. Because of a chemical reaction that occurs when the plaster is wet, the cast feels hot when applied for about 30 minutes and then feels cool, taking anywhere from 24 to 72 hours to completely dry. The cast is dry when it feels hard and firm, is odorless, and is shiny white. Keep the wet cast open to air, and turn the patient about every 2 hours to expose all sides of the cast to the air to aid in drying and to prevent mold growth. A wet cast should be handled with the palms of the hand (“palming the cast”) to prevent indentations or a change in the shape of the cast (Fig. 46.3). This prevents the possibility of pressure points forming inside the cast. Unlike plaster of Paris, synthetic material casts such as fiberglass harden quickly and dry in less than 2 hours.

A casted limb is elevated for 24 to 48 hours, and ice can be applied over the injury to reduce swelling. Observe the cast for dryness, tightness, drainage, and odor. A serious complication of a cast being too tight is compartment syndrome (discussed later). If the cast becomes too tight, the HCP orders it to be cut (bivalved) with a cast cutter to relieve pressure and prevent pressure necrosis of the underlying skin (Fig. 46.4). If a wound is present or an odor is detected, a window opening into the cast is created to treat the underlying skin problem, often an infected area. The cast window should always be taped in place when wound care is not being provided to prevent the skin from “popping up” through the window and developing pressure points and ischemia. Box 46-2 describes nursing interventions for a patient with a cast.

FIGURE 46.3 A wet plaster cast is moved with the palms of the hand to prevent making indentations in the plaster that could become pressure points.

FIGURE 46.4 Bivalving a cast with a cast saw.
Box 46-2 Nursing Interventions for a Patient With a Cast

1. Assess color, warmth, circulation, and movement (CWCM) every 1 to 2 hours for 24 hours and then qid and prn.
   a. Assess cast for tightness (ask patient) and for rough or frayed edges (can interfere with skin integrity).
   b. Make sure patient can move (wiggle) all digits distal to the cast.
2. With newly applied casts (wet):
   a. Never grasp a wet cast to hold or move it, and do not place it on any surface that can cause an indentation. Use only the palms of the hands, because finger pressure on a wet cast can cause pressure points on the inside surface.
   b. Make sure patient is turned every 1 to 2 hours to prevent flattening of cast surface during drying.
   c. With hip spicas or any cast with an abductor bar, do not use bar to move limb or to help with turns.
   d. Inform patient that plaster casts give off heat when drying. Make sure cast air dries (may require 24 to 72 hours for complete drying). Do not cover cast or use drying aids such as blow dryers. Place cast on absorbent surfaces, not plasticized pillows.
   e. Protect skin integrity by ensuring rough edges of cast are properly covered.
   f. Make sure patient knows to keep cast dry during bathing by covering with plastic and preventing water from seeping into cast ends.
   g. Synthetic casts (e.g., fiberglass) can be exposed to water (e.g., for hydrotherapy) as needed but require complete drying afterward.
3. Maintain tissue integrity within the cast.
   a. When assessing CWCM, assess visible skin for signs of impaired integrity.
   b. Cast edges can be smoothed and covered with stockinettes or gauze and tape (make sure there are no tape allergies) to prevent rubbing of skin.
   c. Monitor for signs and symptoms of infection, such as foul odor, heat, redness, and pain.
   d. Do not use skin products on affected limb.
   e. Monitor visible blood on the surface of the cast. Outline area with a pen to observe for increasing size. Shadowing of blood not quite reaching the surface of the cast is fairly common but also should be circled and monitored.
   f. Never place any object inside the cast, and instruct patient not to do so. Explain the risk of skin damage.

Traction. Traction is the application of a pulling force to part of the body to position and hold bone fragments in correct alignment. Advances in orthopedic surgery have decreased the use of traction.

Skin traction. Buck’s traction is skin traction that is used for patients with hip fractures who are not candidates for early surgery. It is commonly applied for comfort to relieve muscle spasms and to prevent further injury while the patient waits for surgery. With skin traction, the amount of weight that can be applied directly on the skin is about 5 to 10 lbs (2.2–4.5 kg).

Skeletal traction. Skeletal traction uses pins, wires, or tongs inserted into the bone for bone alignment as the fracture heals (Fig. 46.5). Heavier weights from 20 to 40 lb (9–18 kg) are used. Skeletal traction must be maintained with weights hanging freely at all times. Neurovascular and skin checks are done regularly. Pin site care is discussed later.

External fixation. External fixation (EF) is used when bone damage is severe, as in crushed or splintered fractures, or if the bone has numerous breaks. After the fracture is reduced, the surgeon inserts pins into the bone. The pins are held in place by an external metal frame to prevent bone movement (Fig. 46.7). EF allows visualization of soft tissue damage that also requires treatment. Pin sites are monitored for infection. Pin-site care varies by agency. The main principle is to ensure that strict aseptic technique is always maintained because the pin is a pathway for microorganisms to directly enter bone tissue and cause osteomyelitis (see the “Nursing Care Plan for the Patient With External Fixation of the Lower Extremity”).

**FIGURE 46.7** External fixation for complex fractures and wound care.

---

**NURSING CARE PLAN** for the Patient After Open Reduction With Internal Fixation of the Hip

**Nursing Diagnosis:** *Pain* related to surgical incision

**Expected Outcome:** The patient will state that pain relief is satisfactory.

**Evaluation of Outcome:** Does patient state that pain is absent or at a tolerable level (pain rated 0 to 2 on pain assessment scale)?

<table>
<thead>
<tr>
<th>Intervention</th>
<th>Assess pain level every 2–4 hours or as needed and with each interaction. <strong>Rationale</strong> Frequent pain assessment provides baseline and ongoing data and allows for timely interventions. <strong>Evaluation</strong> Does patient indicate pain or pain relief?</th>
</tr>
</thead>
<tbody>
<tr>
<td>Intervention</td>
<td>Give analgesics as needed; anticipate need for pain relief. <strong>Rationale</strong> Analgesics relieve pain, especially if given before pain is severe. <strong>Evaluation</strong> Does patient state pain is relieved?</td>
</tr>
<tr>
<td>Intervention</td>
<td>Give analgesics before activity (e.g., session with physical therapist). <strong>Rationale</strong> Increased activity can cause pain. <strong>Evaluation</strong> Is patient restless or agitated during activity?</td>
</tr>
<tr>
<td>Intervention</td>
<td>Use pain relief measures, such as distraction, guided imagery, other relaxation techniques. <strong>Rationale</strong> Analgesic therapy is enhanced with complementary pain relief measures. <strong>Evaluation</strong> Does patient report pain relief with music or relaxation?</td>
</tr>
<tr>
<td>Intervention</td>
<td>Use fracture bedpan. <strong>Rationale</strong> Fracture bedpans are more comfortable and easier to position for patients. <strong>Evaluation</strong> Is patient able to use fracture pan with comfort?</td>
</tr>
</tbody>
</table>
### NURSING CARE PLAN for the Patient After Open Reduction With Internal Fixation of the Hip—cont’d

**Nursing Diagnosis:** Impaired Physical Mobility related to surgical pain  
**Expected Outcome:** The patient will maintain desired level of activity.  
**Evaluation of Outcome:** Does patient maintain activity desired?

<table>
<thead>
<tr>
<th>Intervention</th>
<th>Observe level of physical mobility with each interaction, and as needed. <strong>Rationale</strong> Early and frequent data collection provides baseline data and allows for timely interventions. <strong>Evaluation</strong> Is the patient able to transfer and ambulate? With or without assistance?</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Intervention</strong></td>
<td>Reinforce transfer and ambulation techniques. <strong>Rationale</strong> Activity is restricted because of hip precautions and weight-bearing limitations. <strong>Evaluation</strong> Does patient use trapeze bar for movement in bed with less pain?</td>
</tr>
<tr>
<td><strong>Intervention</strong></td>
<td>Monitor patient for and take measures to prevent complications of immobility: • Turn patient every 2 hours and check skin. • Keep heels off bed. • Teach patient to deep breathe and cough every 2 hours. • Teach use of incentive spirometer. <strong>Rationale</strong> Immobility complications can occur if preventive measures are not used. <strong>Evaluation</strong> Does patient experience complications of immobility?</td>
</tr>
<tr>
<td><strong>Intervention</strong></td>
<td>Apply thigh-high elastic stockings or sequential compression device to unaffected limb as ordered. Remind patient to practice leg exercises. Give anticoagulants as ordered. Get patient out of bed as soon as ordered. Ambulate patient as early as possible. <strong>Rationale</strong> These precautions and activities help prevent blood clots. <strong>Evaluation</strong> Is patient free from blood clots?</td>
</tr>
</tbody>
</table>

### NURSING CARE PLAN for the Patient With External Fixation of the Lower Extremity

**Nursing Diagnosis:** Risk for Infection related to open skin at pin site  
**Expected Outcome:** The patient does not develop an infection.  
**Evaluation of Outcome:** Does patient remain free from infection?

<table>
<thead>
<tr>
<th>Intervention</th>
<th>Inspect dressings, wounds, pin sites for signs and symptoms of infection (warmth, redness, heat, edema, drainage, pain). <strong>Rationale</strong> Early and frequent inspection allows for timely intervention to prevent infection. <strong>Evaluation</strong> Are any wounds infected?</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Intervention</strong></td>
<td>Monitor color, odor and amount of pin site drainage. <strong>Rationale</strong> Pin site drainage color and amount can indicate infection. <strong>Evaluation</strong> Does pin site have purulent drainage?</td>
</tr>
<tr>
<td><strong>Intervention</strong></td>
<td>Provide pin site care per agency policy using aseptic technique. <strong>Rationale</strong> Use of aseptic technique reduces risk of infection. Pin sites should be free of crusting, which promotes infections. <strong>Evaluation</strong> Are pin sites clean with no crusting?</td>
</tr>
<tr>
<td><strong>Intervention</strong></td>
<td>Monitor blood pressure, pulse, and temperature frequently. <strong>Rationale</strong> Increases in blood pressure, pulse, and temperature can indicate infection. <strong>Evaluation</strong> Are vital signs within baseline findings?</td>

</tbody>
</table>
CRITICAL THINKING

Mrs. Martinez

Mrs. Martinez, a care-center resident, was found lying on her left side, moaning and holding her left leg at 1000. She cried out with any movement, and said she fell and broke her leg. The supervisor notified paramedics and Dr. Haas. Vital signs are blood pressure 150/84 mm Hg, pulse 100 beats per minute, and respirations 20 per minute. Her left leg is noticeably shorter than her right leg. The licensed practical nurse (LPN) remained with Mrs. Martinez and instructed her not to move until help arrived. The LPN got blankets and a pillow for her head. The paramedics took Mrs. Martinez to nearby Memorial Hospital, where she was diagnosed as having an incomplete femoral neck (hip) fracture. Dr. Haas ordered 5 pounds of Buck’s traction until surgery the next morning.

Later, Mrs. Martinez is restless and picking at her bedcovers when the nurse arrives to assess her at the beginning of the nurse’s shift.

1. How should the LPN document the incident of Mrs. Martinez’s fall at the care center?
2. What is the purpose of Buck’s traction for Mrs. Martinez?
3. What are the nursing responsibilities while caring for Mrs. Martinez?
4. What might explain Mrs. Martinez’s restlessness? 

Suggested answers are at the end of the chapter.

CRITICAL THINKING

Frank Schnell

Frank, age 18, was in a motor vehicle accident that resulted in a fractured pelvis and an open right femoral fracture.

1. Identify four priority nursing diagnoses related to Frank’s care.
2. What are nursing interventions and rationales for these diagnoses?
3. How can the constipating effects of opioids be balanced with the benefits of pain relief to manage bowel elimination (see Chapter 10)?

Suggested answers are at the end of the chapter.

NONUNION MODALITIES. Although most bones heal properly with the correct treatment, some patients experience malunion (malalignment of healed bone) or nonunion (delayed or no healing). Several factors influence how a bone heals, including age, nutritional status, and diseases that alter the healing process, such as diabetes mellitus. Identification of the reason for nonunion allows appropriate treatment selection. Treatment methods for nonunion can include electrical bone stimulation, bone grafting or external fixation.

Complications of Fractures

Monitor the patient for possible complications, such as impaired neurovascular status, hemorrhage, infection, and thrombi. Although rare, acute compartment syndrome and fat embolism syndrome (more common with fractures of long bones) can be life-threatening complications of fractures.

NEUROVASCULAR STATUS. Neurovascular checks are done as needed to detect abnormalities. Decreased or absent pulses, cool skin temperature, and dusky color indicate circulation alterations. Numbness and tingling, decreased sensation, and mobility indicate neurologic alterations. These findings should be reported to the HCP immediately.

HEMORRHAGE. Bone is highly vascular, and damage to or surgery on bone (particularly the large long bones of the extremities) can cause bleeding. Check for bleeding and monitor vital signs carefully. Hypovolemic shock may result from severe hemorrhage (see Chapter 9).

INFECTION. Trauma predisposes the body to infection, especially when the skin, the body’s first line of defense, is disrupted. Wound infections, pin-site infections, drainage tube infections, and osteomyelitis (bone infection) are common.

VENOUS THROMBOEMBOLIC COMPLICATIONS. Deep venous thrombosis (DVT) or pulmonary embolus (PE; see Chapter 31) can develop in patients who are immobile because of trauma or surgery. Thromboembolic complications are the most common problems of lower extremity surgery or trauma and the most fatal complication of musculoskeletal surgery, particularly in the older adult. Leg exercises, early ambulation, and prophylactic anticoagulant therapy such as with dalteparin (Fragmin), enoxaparin (Lovenox), fondaparinux (Arixtra), or rivaroxaban (Xarelto), help prevent these problems.

ACUTE COMPARTMENT SYNDROME. Compartments are sheaths of fibrous tissue that support and partition nerves, muscles, and blood vessels, primarily in the extremities (Fig. 46.8). Each extremity has several compartments. Acute compartment syndrome is a limb-and life-threatening condition.
in which pressure in one or more limb compartments increases, causing reduced circulation to the compartment’s muscles and nerves. An EF device such as a cast or bulky dressing can increase pressure when there is tissue swelling or compression in the area. The early symptom of acute compartment syndrome is the patient’s report of severe, increasing pain that is not relieved with opioids and occurs more in active movements than passive movements. Decreased sensation follows before ischemia becomes severe. In severe acute compartment syndrome, the patient has the six P’s:

1. Pain (severe, unrelenting, and increased with passive stretching)
2. Paresthesia (painful tingling or burning)
3. Paralysis (late symptom)
4. Pallor (but there may be warmth or redness over the area)
5. Pulselessness (late and ominous sign)
6. Poikilothermia (temperature matches environment; i.e., the extremity is cool to touch).

Relief of pressure is the goal. It may be accomplished by removing the source of pressure, such as by bisecting a cast, or by performing a fasciotomy, which is an incision into the fascia that encloses the compartment. This incision allows the compartment tissue to expand and relieves the pressure. If more than one compartment has increased pressure, multiple fasciotomies are required. These surgical wounds remain open until the pressure decreases. Then they are closed and could require skin grafting. If this condition continues without pressure relief, tissue necrosis, infection, Volkmann’s contracture (permanent flexion of hand/wrist), rhabdomyolysis (muscle break down releases myoglobin which is harmful to the kidneys), or renal failure may result.

FAT EMBOLISM SYNDROME. Fat embolism syndrome (FES) is another serious complication of fractures in which small fat droplets are released from yellow bone marrow into the bloodstream (Table 46.2). The droplets then travel to the lung fields, causing respiratory insufficiency, which can lead to respiratory failure. This process occurs with long bone fractures (especially the femoral shaft) and perhaps when the patient has multiple fractures. The older adult patient with a fractured hip is also at a high risk for FES. This condition can occur up to 72 hours after the initial injury.

The three primary manifestations of FES are respiratory failure, cerebral involvement, and skin petechiae. Pulmonary
dysfunction is the earliest sign and includes tachypnea, dyspnea, and cyanosis. Cerebral changes are often seen and include confusion or drowsiness. A petechial (red, measles-like) rash on the chest, neck, axilla, and conjunctiva appears in some patients. Other signs include tachycardia, fever, and retinal changes. If a fat embolism is suspected, these actions should be taken as ordered:

1. Notify the HCP immediately.
2. Promote oxygenation by administering oxygen at 2 L/min via nasal cannula, and apply a pulse oximeter.
3. Place the patient in high-Fowler’s position or raise the head of the bed as tolerated.
4. Maintain bed rest, and minimize movement of the extremity.
5. Obtain arterial blood gas (ABG).
6. Initiate venous access, then administer IV.
7. Administer corticosteroids.
9. Provide emotional support and calm environment.

**NURSING CARE TIP**

A patient who is confused or comatose may not be able to report pain, which can be problematic because the most reliable indicator of pain is the patient’s report. Nonverbal indicators (e.g., grimacing, restlessness, elevated blood pressure and heart rate) are not reliable for pain assessment and should not be used to assume the absence of pain.

**NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.**

Determination of the appropriate nursing diagnosis depends on the type of fracture. See the “Nursing Care Plan for the Patient After Open Reduction Internal Fixation of the Hip.”

**Acute Pain related to fractured bone**

**EXPECTED OUTCOME** The patient will report relief from pain using a pain assessment scale.

- Identify pain level on a 0 to 10 pain scale to establish baseline for further interventions.
- Provide analgesics and anti-inflammatories as ordered to relieve pain and swelling.
- Ensure proper positioning and alignment to promote pain relief and future functioning.
- Monitor for compartment syndrome if patient has a cast in place to prevent neurovascular complications.
- Apply ice as ordered to decrease swelling and pain.
- Teach alternative methods for pain relief to maximize relief of pain.

**Impaired Physical Mobility related to bone fracture**

**EXPECTED OUTCOME** The patient will demonstrate increased mobility.

- Observe patient’s mobility to provide baseline assessment data.
- Encourage independence to promote mobility.
- Utilize other disciplines such as occupational and physiotherapy to encourage and promote patient mobility.
- Provide equipment and resources such as crutches and wheelchairs to improve mobility.

**Risk for Peripheral Neurovascular Dysfunction related to increased tissue volume or restrictive envelope**

**EXPECTED OUTCOME** The patient will maintain peripheral pulses, warm skin, sensation, and ability to move extremity.

- Assess often for compartment syndrome to promote prompt reporting.
- Assess for swelling of affected limb (especially if patient has a cast or tight dressing) to detect complications.
- Keep limb elevated above heart to minimize edema.
- Administer anti-inflammatory agents as ordered to reduce pain and swelling.
- Monitor for increasing pain even after analgesic administration to detect complications.

**DATA COLLECTION.** The most important aspect of monitoring the patient with a fracture is frequent checking of neurovascular status (circulation, sensation, mobility) distal to the fracture site to detect problems (see Chapter 45).

Pain is managed by both medications and complementary therapies. Bone pain can be excruciating and must be treated aggressively. For the patient who cannot report pain, such as a patient who is cognitively impaired or comatose, ensure that pain relief is maintained by regularly scheduled analgesic administration.

**NURSING CARE TIP**

Caring for the patient with a fracture requires coordinated teamwork with other health team members.

**Chapter 46** Nursing Care of Patients With Musculoskeletal and Connective Tissue Disorders
EVALUATION.
The outcome is met if the patient reports or demonstrates that pain is within tolerable levels on a pain assessment scale, demonstrates increased physical mobility, and maintains peripheral pulses, warm skin, sensation, and ability to move extremity.

PATIENT EDUCATION.
If the patient has a cast, review appropriate instructions for cast care (see Box 46-2). Health teaching is also important for care of the extremity after cast removal (Box 46-3). If the patient has a wound, teach patient and caregiver how to assess and dress the wound, including pin care if needed, and when to report changes, such as signs and symptoms of infection. Teach the importance of adequate protein, calories, vitamins, and minerals in healing.

Osteomyelitis
Osteomyelitis is an infection of bone that can be either acute (lasts less than 4 weeks) or chronic (lasts more than 4 weeks).

Pathophysiology
Bone infection results from invasion of bacteria into the bone and surrounding soft tissues. Inflammation occurs, followed by ischemia (decreased blood flow; Fig. 46.9). Bone tissue then becomes necrotic (dies), which retards healing and causes more infection, often as a bone abscess.

Etiology
Pathogens enter bone in several ways. Injury to the body allows the offending microbes direct access to bone tissue. An open fracture is an example of that process. Infection beginning in another part of the body can migrate to a bone. For instance, a patient with a total hip replacement may acquire osteomyelitis from a urinary tract infection. The most common pathogen causing osteomyelitis is Staphylococcus aureus.

Signs and Symptoms
The patient with acute osteomyelitis has fever, as well as local signs of inflammation, such as tenderness, redness, heat, pain, and swelling. Pain (particularly over the area of infection), may be the only apparent patient concern. Ulceration, drainage, and localized pain are typical signs and symptoms of chronic osteomyelitis.

Diagnostic Tests
The patient with osteomyelitis typically has an elevated white blood cell (WBC) count, an elevated ESR, positive bone biopsy for infection, and possibly a positive blood culture. MRIs, x-rays, and CT scans show infected areas.

Therapeutic Measures
Long-term antibiotic therapy (4–6 weeks) is the treatment of choice for patients with osteomyelitis. Infection in bone tissue is difficult to resolve. Surgery to remove necrotic bone tissue or replace it with healthy bone tissue can also be needed. Amputations are reserved for patients who have massive infections that have not responded to one or more of the conventional treatments.

Nursing Care
Patients receive the IV antibiotics at home. Patients and caregivers require teaching about side effects, toxicity, interactions,
and precautions for antibiotic therapy. A home health nurse often assists the patient.

If a soft tissue wound is present, ensure that sterile technique is used for dressing changes. The home health nurse teaches the patient and family how to perform dressing changes, the importance of hand hygiene before dressing changes, and how to avoid the spread of pathogens.

Osteoporosis

Osteoporosis (porous bone) is a metabolic disorder in which there is low bone mass and deterioration of bone structure, resulting in fragile bones that are prone to fracture. The spine, wrist, and hip are most commonly involved although all bones can be affected.

Prevalence

More than 57 million people have osteoporosis, or low bone density (National Osteoporosis Foundation, 2013). Women are at greatest risk because their bones are smaller than men’s bones. As the U.S. population ages, the incidence and cost of osteoporosis will rise. By 2020, half of all Americans over age 50 may have weak bones. This is significant because hip or vertebral fractures are associated with reduced quality of life, increased disability, and increased risk of death, especially within the year after the fracture.

Pathophysiology

Bone is living tissue that is resorbing (breaking down) old bone tissue (osteoclast cells) and constantly building new bone tissue (osteoblast cells). Normally, this bone remodeling process is balanced. In osteoporosis, an imbalance results. Bone density (mass) peaks between ages 30 and 35. After these peak years, the rate of bone breakdown exceeds the rate of bone buildup. For postmenopausal women, decreased estrogen appears to slow the absorption of calcium, leading to increased bone loss.

Types and Risk Factors

Osteoporosis is categorized as either primary or secondary. Primary osteoporosis is the most common and is not associated with another disease. Some risk factors for primary osteoporosis can be controlled but others cannot. Those that are not controllable include the following:

- Female gender
- Aging
- Caucasian or Asian
- Small boned, petite body build
- Postmenopausal status
- Low testosterone and estrogen in men
- Family history of osteoporosis or fractures
- History of fractures

Risk factors related to lifestyle that are controllable include:

- Cigarette smoking
- Excessive alcohol consumption
- Anorexia nervosa
- Nutrition: low calcium or vitamin D intake, excessive caffeine, protein, or sodium intake
- Sedentary lifestyle

For a Personal Bone Profile Questionnaire, visit www.niams.nih.gov/Health_Info/Bone/Optool/index.asp.

Secondary osteoporosis results from an associated medical condition or procedure, such as hyperparathyroidism; renal dialysis; drug therapy with steroids, certain antiseizure drugs, sleeping medications, aluminum-containing antacids, hormones for endometriosis, or cancer drugs; and prolonged immobility, such as that seen with patients who have a spinal cord injury.

Prevention

To protect against osteoporosis, practicing healthy lifestyle and nutritional habits that build bone are especially important.
through age 30, before bone mass begins to decrease. These habits should include consuming recommended amounts of calcium (1000 mg/day for ages 4–8, and 1300 mg/day for ages 9–18) and vitamin D (600 mg/day for ages 4–18); performing weight-bearing and muscle-strengthening exercises, especially in childhood; avoiding alcohol; and not smoking.

**Signs and Symptoms**

Most people do not realize they have osteoporosis until they fracture a bone falling, sustaining a mild bump, or sneezing. With vertebral compression fractures, a decrease in height (up to 6 inches), severe back pain, and the classic “dowager’s hump,” or kyphosis of the spine, is present as the spine begins to collapse. The patient may be embarrassed by the change in body image and may have curtailed social activities. Some patients have difficulty finding clothes that fit comfortably.

General effects of the disease go beyond the obvious bone deformities. Quality of life can be affected. Acute or chronic pain may occur. Physiological effects can include decreased respiratory capacity due to spinal deformities. It can be difficult to expand the lungs because of curvature of the spine or painful vertebral fractures. This can increase fatigue and the risk of pneumonia. Osteoporosis can be associated with chronic obstructive pulmonary disease (COPD) because of limited activity related to dyspnea and corticosteroid therapy (which breaks down bone).

Functional abilities (ADLs and instrumental activities of daily living [IADLs]) may be limited, which increases the patient’s dependence. Emotional effects can relate to body image changes, depression, or anxiety from fear of breaking a bone including during intimacy. Socialization may be reduced because of activity limitations or fear of injury. Because these effects are interrelated, the whole person, not just the disease, needs to be assessed and treated to improve quality of life.

**Diagnostic Tests**

Dual-energy x-ray absorptiometry (DEXA) is the standard screening tool to measure bone density (“Gerontological Issues”). This noninvasive scan is a low-dose x-ray and takes about 5 minutes to perform while the patient lies on a table. A DEXA scan identifies low bone density at the hip and spine. It can show response to treatment.

Serum calcium and vitamin D values can be decreased, and serum phosphorus may be increased. With severe bone loss, alkaline phosphatase levels may be elevated, confirming bone damage.

**Therapeutic Measures**

There is no cure for osteoporosis, but it can be treated. The cornerstone of treatment for osteoporosis is medication and controlling risk factors to prevent bone loss.

**MEDICATION.** Supplements and medication are used for prevention or treatment. These include calcium supplements, vitamin D, antiresorptive drugs, and bone-forming drugs.

Calcium is important to prevent bone loss. If serum calcium falls below normal levels, the parathyroid glands stimulate bone to release calcium into the bloodstream. The result is demineralized bone. Therefore, calcium supplements to maintain normal levels are important. The patient should be taught to drink plenty of fluids to prevent calcium-based urinary stones. Vitamin D supplementation, to aid calcium absorption, also may be needed, especially for patients who have reduced exposure to sunlight (residents of extended care facilities or northern geographical areas, for example) or who cannot metabolize vitamin D.

**Antiresorptive Medications.** Bisphosphonates are used to prevent or slow the progress of osteoporosis. They bind to bone and suppress osteoclast activity to prevent or reduce the breakdown process. They include alendronate (Fosamax, Fosamax Plus D), ibandronate (Boniva), risedronate (Actonel), and zoledronic acid (Reclast). Bisphosphonates have been shown to be effective for at least 10 years. However, over time bone loss still continues.

Side effects of bisphosphonates include bone, muscle, or joint pain; gastrointestinal (GI) upset; gastric ulcers; and rarely osteonecrosis (bone death) of the jaw. Teach the patient specifically how to take each medication to reduce side effects. Typically, the tablet or solution form is taken in the morning after awakening on an empty stomach. It is followed by a full glass of water (only water) with nothing else to eat or drink for up to 1 hour. The patient should not lie down for at least 30 minutes to 1 hour after taking the drug.

Calcitonin (Fortical, Micalcin) is a synthetic thyroid hormone and treats osteoporosis by decreasing bone loss. It is used for women who have been menopausal for 5 years.

Denosumab (Prolia) is a monoclonal antibody that inhibits the protein that signals bone removal. Raloxifene (Evista) is a selective estrogen receptor modulator (SERM) that increases bone mass by 2% to 3% each year. SERM drugs are designed to mimic estrogen in some parts of the body while blocking its effects elsewhere.

Estrogen therapy may be used to prevent the bone loss that occurs with menopause as estrogen levels fall. However, other treatments should be considered first due to risk factors associated with estrogen therapy.

**Anabolic (Bone-Forming) Medications.** Teriparatide (Forteo) is used for men and women at great risk for fracture. Teriparatide increases bone mass by increasing the action and number of osteoblasts that form bone. It should not be taken for more than 2 years.

**DIET.** Increasing calcium and vitamin D intake are the main dietary considerations. Generally, calcium intake should be...
1000 mg/day for those ages 18 to 49 and 1200 mg for those over age 50. Teach patients which foods are high in calcium, such as dairy products (yogurt and skim milk may have low levels) and dark green, leafy vegetables.

**EXERCISE.** Exercise in childhood is essential in preventing osteoporosis. Weight-bearing exercise, especially walking, stimulates bone building. The patient should wear well-supporting, nonskid shoes at all times and a void uneven surfaces that could contribute to falls. Resistance exercise such as weight training is also beneficial (“Gerontological Issues”).

**Fall Prevention**

Osteoporotic bone may cause a pathological fracture, in which the hip breaks before the fall. For other patients, a fall can cause a hip or other fracture. Therefore, fall prevention programs in hospitals and extended care facilities are important.

In collaboration with the physical or occupational therapist, case manager, or discharge planner, assess the patient’s home environment. Patient and family are taught how to create a hazard-free environment, such as avoiding scatter rugs and slippery floors. Walking paths in the home must be kept free of clutter to prevent falls. If needed, a walker or cane provides additional support.

**Nursing Care**

Nursing care for osteoporosis focuses on education for prevention, providing pain relief and support for symptoms, and medication teaching. For more information, visit the National Osteoporosis Foundation at www.nof.org.

**Paget’s Disease**

Paget’s disease is a metabolic bone disease in which there is increased breakdown and formation of bone that results in abnormally formed, weak bones, causing deformities, bone pain and fractures, and osteoarthritis (www.paget.org). Paget’s disease affects mainly older adults and men. The most common areas in involved are the spine, femur, skull, and pelvis. X-rays show bones with punched-out areas. Bone scan shows how widespread the disease is. An increased serum alkaline phosphatase level occurs due to osteoblast activity. Pain is a major symptom in many. Other symptoms based on the bone affected include limping, joint stiffness, and a pinched nerve with numbness and tingling.

There is no cure for Paget’s disease, but medications are used to relieve pain and promote quality of life. NSAIDs are given for pain control, bisphosphonates reduce bone resorption and calcitonin (Fortical, Miacalcin), a synthetic thyroid hormone, decreases bone loss. Exercise maintains bone health and joint mobility. For uncontrolled pain, surgery such as joint replacement can be done. Nursing care aims to provide pain relief, supportive symptom care and education.

**Bone Cancer**

Bone tumors may be benign or malignant. Malignant tumors may be either primary (originating in the bone) or metastatic, originating from another location and migrating to bone. Metastatic lesions are more common and most often affect older adults.

**Primary Malignant Tumors**

Osteosarcoma, or osteogenic sarcoma, is the most common primary malignant bone tumor as well as being the most fatal bone tumor. It is a fairly large tumor that typically metastasizes to the lung within 2 years of diagnosis and treatment. It usually affects young people between ages 10 and 25, and boys are twice as likely to develop the disease. Long bones of the legs (particularly around the knees), and arms are most often the sites of origin but it can be found in other bones. Older patients with Paget’s disease also may develop these lesions. The disease itself is relatively rare, with an occurrence rate of about 2 per million people.

Pain and swelling in an arm or leg that worsens with exercise or at night are some of the manifestations of osteosarcoma. A lump in the area or an unexplained limp also may be cause for further investigation. X-rays, bone biopsy, CT scan, bone scan, and MRI are helpful in diagnosing the malignancy. Chemotherapy and surgical excision of the affected bone with bone grafting, or amputation of the affected limb are the treatments most commonly used for osteosarcomas.

Ewing’s sarcoma is the most malignant bone tumor. In addition to local pain and swelling, systemic signs and symptoms, including low-grade fever, leukocytosis, and anemia, are common. The pelvis and legs are most often affected in children and young men.

Patients with a chondrosarcoma (cancer of cartilaginous cells) have a better prognosis than those with the previously described types of bone cancer. This type of cancer occurs in middle-aged and older people.

**METASTATIC BONE DISEASE.** Primary malignant tumors that occur in the prostate, breast, lung, and thyroid gland are called bone-seeking cancers because they migrate to bone more than any other primary cancer. Once cancer has metastasized, multiple sites in the bone are typically seen. Pathological fractures and severe pain are major concerns in managing metastatic disease (see Chapter 11).

**Signs and Symptoms**

Primary tumors cause local swelling and pain at the site. A tender, palpable mass is often present. Metastatic disease is not
as visible, but the patient reports diffuse severe pain, eventually leading to marked disability.

**Diagnostic Tests**

Diagnosis of bone cancer is made by x-ray, CT scan, bone scan, bone biopsy, or MRI (see Chapter 45). Patients with metastatic disease have elevated alkaline phosphatase levels and possibly an elevated ESR, indicating secondary tissue inflammation.

**Therapeutic Measures**

Management of bone cancer depends on the type and extent of the tumor. The treatment of primary bone tumors is usually surgery, often combined with chemotherapy or radiation. The surgeon attempts to salvage the limb and performs a resection of the tumor. For patients with Ewing’s sarcoma or early osteosarcoma, external radiation may be the treatment of choice to reduce tumor size and pain.

Care of the postoperative patient is similar to that for any patient undergoing musculoskeletal surgery. Monitoring the neurovascular status of the operative limb is a vital nursing intervention (see Chapters 12 and 45).

For metastatic bone disease, surgery is not appropriate. External radiation is given, primarily for palliation. The radiation is directed toward the most painful sites in an attempt to shrink them and provide more comfort for the patient.

**Nursing Care**

Nursing care for the patient with bone cancer is not unlike that for patients with any other type of cancer. Help the patient adjust to the diagnosis, and refer the patient to resources such as the American Cancer Society and support groups (www.cancer.org). Chapter 10 describes the nursing care associated with chemotherapy and radiation therapy.

---

**CONNECTIVE TISSUE DISORDERS**

Connective tissue disorders comprise a group of more than 100 diseases in which the major signs and symptoms result from joint involvement. Some connective tissue diseases affect only one part of the body; others affect many body organs and systems. Several disorders are discussed here, including gout, osteoarthritis, and rheumatoid arthritis.

**Gout**

Gout is an easily treated systemic connective tissue disorder from the buildup of uric acid. Men, especially those middle aged and older, are more often affected than women. Patients with gout are seldom hospitalized for their disease.

**Pathophysiology**

Uric acid is a waste product resulting from the breakdown of proteins (purines) in the body. Urate crystals are formed because of excessive uric acid buildup (hyperuricemia) and are deposited in joints and other connective tissues, causing severe inflammation. When an “attack” of gout occurs, the patient has severe pain and inflammation in one or more small joints, usually the great toe. The inflammation may resolve in several days, with or without treatment. Months or years may pass between attacks, and the patient may have no signs or symptoms of joint inflammation between episodes. Urate deposits (tophi) occasionally appear under the skin (outer ear commonly; Fig. 46.10) or in the kidneys or urinary system, causing stone (calculi) formation (see Chapter 37).

**Etiology and Types**

Primary gout is the most common type of gout and is caused by an inherited problem with purine metabolism. Uric acid production is greater than the kidneys’ ability to excrete it. Therefore, the amount of uric acid in the blood increases. Acute attacks of gout may be triggered by stress, alcohol consumption, illness, trauma, dieting, or certain medications.

Patients with secondary gout also experience hyperuricemia, but the increase is the result of another health problem, such as renal insufficiency, or medications, such as diuretic therapy and certain chemotherapeutic agents.

**Signs and Symptoms**

**ACUTE GOUT.** Patients with acute gout have one or more severely inflamed joints due to the uric acid crystals, usually small joints, often in the joint of the great toe. The joint is swollen, red, hot, and usually too painful to be touched.

**CHRONIC GOUT.** Patients with chronic gout may not have obvious signs and symptoms. Renal stones can develop from elevated uric acid.

**Diagnostic Tests**

Diagnosis of gout is based on an elevated serum uric acid level. Joint fluid aspiration analysis can also identify uric acid crystals in the synovial fluid.

---

**WORD BUILDING**

hyperuricemia: hyper—excessive + uric—uric acid + emia—in blood

---

Therapeutic Measures

**MEDICATION.** Drug therapy is the first-line treatment for primary gout. Treatment for secondary gout involves management or removal of the underlying cause. For an acute gout episode an NSAID, colchicine (Colcrys) or steroids are prescribed until the joint inflammatory response to the urate crystals subsides. If these medications are not tolerated or effective, pegloticase (Krystexxa) by IV infusion can be given every 2 weeks.

Uricosuric agents (medications used to decrease uric acid) are the drug of choice to prevent increased serum uric acid levels. Febuxostat (Uloric) and allopurinol (Zyloprim) decrease uric acid production. The patient must take these drugs every day to keep the uric acid level within the normal range. Probenecid (Benemid) may also be used temporarily to increase renal excretion of uric acid. Serum uric acid level is monitored periodically.

**DIET.** Certain foods should be avoided or consumed in moderation (Box 46-4). Aspirin, diuretics, and alcohol (especially beer) should be avoided because they can trigger a gout attack. Increasing daily fluid intake helps prevent kidney stones.

Osteoarthritis

Osteoarthritis (OA) is the most common type of connective tissue disorder, affecting more than 20 million people in the United States. It is also referred to as degenerative joint disease.

**Pathophysiology**

OA occurs when the articular cartilage and bone ends of joints slowly deteriorate due to “wear and tear,” a normal result of aging (Table 46.3). The joint space narrows, bone spurs develop, and the joint may become some what inflamed. The body’s repair process is not able to overcome the loss of cartilage and bone, resulting in pain, swelling and stiffness. Weight-bearing joints (hips and knees), hands, and the vertebral column are most often affected (Fig. 46.11).

- Disturbed Body Image

**Priority Nursing Diagnoses**

- Chronic Pain
- Self-Care Deficits
- Ineffective Health Maintenance

**FIGURE 46.11** Common joints affected by osteoarthritis and the changes that result in the joint.
Etiology and Types

The most common type of OA is primary (idiopathic) osteoarthritis. The cause of OA is unknown, but several risk factors have been identified. Aging, obesity, and physical activities that create mechanical stress on synovial joints are major risks. Most people over age 60 have some degree of symptomatic joint degeneration. Native Americans are affected more often than other groups. The reason for this is unknown.

Patients with secondary OA develop joint degeneration as a result of trauma, sepsis, congenital anomalies, certain metabolic diseases (such as Paget’s disease), or systemic inflammatory connective tissue disorders such as rheumatoid arthritis.

Signs and Symptoms

The patient usually seeks medical attention when joint pain and stiffness become severe or the patient has problems with everyday activities. One or more joints may be affected, most commonly in the hands, hips, knees, spine, and feet. Joint pain intensifies after physical activity but lessens following rest. If the vertebral column is involved, the patient reports radiating pain and muscle spasms in the extremity innervated by the area affected.

About half of patients with OA have bony nodes on the joints of their fingers, called Heberden’s and Bouchard’s nodes. Women tend to have them more often than men. They can be painful. The nodes have a familial tendency and often are a cosmetic concern to female patients.

Diagnostic Tests

X-ray examinations are useful in outlining joint structure and detecting bone changes. A CT scan or MRI is used to diagnose joint involvement. Analysis of synovial fluid can aid in the diagnosis of OA while ruling out other pathological joint conditions.

Therapeutic Measures

There is no cure for OA. Pain control is the focus of treatment, which is accomplished by drug therapy, other pain relief measures, or ultimately surgery. An interdisciplinary approach is needed to prevent decreased mobility and preserve joint function.

Evidence-Based Practice

Clinical Question

Does acetaminophen work as well or better than NSAIDs when administered for the pain of arthritis?

Evidence

A systematic review of 273 studies looked at the comparative effectiveness, benefits, and adverse effects of analgesics used for osteoarthritis. It was found that acetaminophen does not reduce arthritis pain quite as well as NSAIDs. Each drug class is not without risks. NSAIDs carry GI and cardiovascular risks. Acetaminophen can be toxic to the liver. Topical NSAIDs are effective but can have skin side effects.

Implications for Nursing Practice

Each patient should be encouraged to develop an effective individualized treatment plan with their HCP based on health factors, concurrent medications, family history, body mass index (BMI), age, disease advancement, and effectiveness of pain medication. Adverse effects to report should be taught by the nurse.

REFERENCE

CRITICAL THINKING

Mr. Finn

Mr. Finn, a 59-year-old hardware store manager, is 5’11” and weighs 250 pounds. He visits his HCP because of knee pain. He has noticed that it is becoming increasingly difficult to bend to pick up heavy boxes. The HCP suspects osteoarthritis.

1. What data collection questions should be included in this patient’s history?
2. What risk factors does the patient have?
3. What other signs and symptoms might Mr. Finn have?
4. What are patient-centered care interventions for Mr. Finn?
5. What health care team members can provide collaborative care?

Suggested answers are at the end of the chapter.

Medication

Drug therapy is commonly used to reduce pain in patients with OA (see “Evidence-Based Practice”). Often, it is combined with other pain-reducing therapies. The most commonly used drugs are NSAIDs (Table 46.4). These drugs have analgesic and anti-inflammatory effects. Common side effects include GI distress and bleeding, which can be severe; and sodium and fluid retention. They also may increase the risk of cardiovascular events, such as myocardial infarction or stroke. Older patients taking NSAIDs on a routine basis should...

which makes prostaglandins that produce inflammation, fever, pain; support platelets; and protect stomach lining (COX-1 only).

T-Cell Modulators
Reduce activation of T cells in the inflammatory process.

be carefully monitored for heart failure and hypertension from fluid retention. Over-the-counter topical creams such as capsaicin (ArthriCare) can be applied to the joints.

REST AND EXERCISE. Joint pain from OA tends to decrease with rest; therefore, pain is less severe in the morning. Activities should be scheduled at this time. A severely inflamed joint may be splinted by the OT or PT to promote rest to a selected joint. However, rest must be balanced with exercise to prevent muscle atrophy from disuse. Exercise has been identified as a means to maintain general health and weight, ROM, and muscle strength, while decreasing anxiety and depression. To minimize muscle atrophy and to stabilize and protect arthritic joints, patients should be encouraged to perform exercises to strengthen their quadriceps if they have OA of the knee.

Joints should always be placed in their functional position—that is, a position that does not lead to contractures. For example, only a small pillow should be placed under the head when sleeping to prevent excessive neck flexion.

HEAT AND COLD. The patient with OA usually prefers heat therapy unless the joint is acutely inflamed. Hot packs, warm compresses, warm showers, moist heating pads, and paraffin dips provide sources of heat. Cold therapy minimizes inflammation while altering cutaneous pain receptors, thereby decreasing pain. Cold packs should be applied for no longer than 20 minutes at a time.

DIET. Obese or overweight patients benefit from losing weight to decrease stress on weight-bearing joints and thereby reduce pain. If the patient is on medications that can alter fluid volumes (corticosteroids), a diet low in sodium may be appropriate.

COMPLEMENTARY AND ALTERNATIVE THERAPIES. The popularity of complementary and alternative therapies to reduce pain and stress has grown tremendously. Imagery, music therapy, acupressure, acupuncture, and other holistic modalities that foster the mind-body-spirit connection work well for many people.

SURGERY. If the patient’s pain cannot be managed successfully, a total joint replacement (TJR) may be indicated. TJR is the most common type of arthroplasty (see later section on musculoskeletal surgery).

Nursing Process for the Patient With Osteoarthritis

DATA COLLECTION. The patient’s report of pain is noted and affected joints observed for signs of inflammation or deformity. Also examined are joint function, alterations in ADLs, and mobility (“Gerontological Issues”).

WORD BUILDING

arthroplasty: arthro—joint + plasty—creation of

Gerontological Issues

OA affects millions of Americans. Because of the large number of people with this condition, it is recommended that nurses check for OA even when it is not the admitting
diagnosis to help identify functional deficits and treatment needs.

OA treatment focuses on pain management and functional ability. In addition, interventions that have been shown to help a hospitalized older adult patient after discharge include:

- Identifying a social support system
- Teaching medication side effects as well as interactions that may cause bleeding
- Encouraging participation in occupational and physical therapy
- Referring to a nutritionist for weight loss if indicated
- Referring for cognitive-behavioral therapy for pain management and coping as prescribed.

NURSING DIAGNOSES, PLANNING, IMPLEMENTATION, AND EVALUATION.

Chronic Pain related to chronic inflammatory disease

**Expected Outcome:** The patient will state that pain is within tolerable levels on a pain assessment scale of 0 to 10.

- Ask patient to rate pain on a scale of 0 to 10 to determine level of pain and need for pain relief.
- Provide analgesics as ordered to help alleviate painful sensations.
- Collaborate with interdisciplinary team such as pain clinic to explore alternative pain relief measures.
- Consider alternative methods of therapy such as guided imagery, distraction, acupuncture, and biofeedback to use all possible methods of pain control.

Activity Intolerance related to pain

**Expected Outcome:** The patient will participate in ADLs as tolerated.

- Monitor pain during activity to provide baseline data for future assessments.
- Encourage as much independence as possible to promote activity.
- Assist with ADLs as needed to ensure that patient does not become exhausted.
- Provide pain relief measures before activity to enable an increase in activity level.
- Ensure nursing interventions are grouped together to minimize patient exertion.
- Collaborate with interdisciplinary team (e.g., occupational therapy, home health physiotherapy) to utilize their resources and knowledge.

Chronic Sorrow related to altered body image, altered role, pain, and ongoing losses

**Expected Outcome:** The patient will verbalize improvement in feelings of sorrow.

- Observe patient’s affect and mood connected to pain and loss to provide baseline data.

- Allow time to discuss feelings and anticipate trigger events to ensure the patient is aware of what may increase feelings of sorrow.
- Encourage use of interdisciplinary team such as social worker, psychologist, clergy, or spiritual adviser to provide alternate methods of dealing with sorrow.
- Encourage use of support groups to enable the patient to discuss concerns with others experiencing the same problems.

**Disturbed Body Image related to changes in joint function and structure**

**Expected Outcome:** The patient will demonstrate acceptance of changes in body image.

- Encourage patient to discuss feelings and concerns so patient knows that nurse understands what patient is experiencing.
- Provide information and clarify misconceptions to ensure that patient is aware of expected problems and concerns.
- Encourage socialization to improve the patient’s perceptions of how he or she appears to others.

Impaired Physical Mobility related to altered joint function and pain

**Expected Outcome:** The patient will demonstrate improved physical mobility.

- Observe mobility capabilities to provide baseline data.
- Administer analgesics and anti-inflammatory agents as ordered to improve joint function and decrease pain.
- Encourage active range-of-motion exercises to prevent or minimize further alteration in joint function.
- Ensure proper positioning and alignment to promote joint function and decrease pain.
- Use interdisciplinary team such as physiotherapy and occupational therapy to utilize resources and knowledge from other sources.

Self-Care Deficit related to chronic degenerative joint disease

**Expected Outcome:** The patient will be able to provide own self-care.

- Observes patient’s self-care abilities to gather baseline data for planning care.
- Encourage independence to decrease feelings of despair about being unable to care for self.
- Assist when necessary to minimize frustration when patient cannot perform self-care.
- Teach patient about assistive devices to help with activities of daily living to promote self-care.
- Collaborate with interdisciplinary team such as social care, occupational therapy, or physiotherapy to acquire assistive devices and use alternate resources.

**EVALUATION.** The outcomes are met if patient reports pain is within tolerable levels on a pain assessment scale of 0 to 10, is able to participate in ADLs, verbalizes improvement in feelings of sorrow, demonstrates acceptance of changes in body image, demonstrates improved physical mobility, and is able to provide own self-care.
PATIENT EDUCATION. A vital function of each member of the health care team is health teaching. The patient with OA is seldom admitted to the hospital for treatment of OA unless surgery is scheduled. However, many patients with OA are admitted for other reasons, and their arthritis needs must also be considered in the comprehensive plan of care. Most patients residing in extended care facilities also have OA, which can affect their participation in recreational activities, as well as ADLs.

Patients can be taught ways to protect their joints and conserve energy. For educational materials and self-help courses, visit the Arthritis Foundation at www.arthritis.org.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, progressive, systemic inflammatory disease that destroys synovial joints and other connective tissues, including major organs.

Pathophysiology

Inflammatory cells and chemicals cause synovitis, an inflammation of the synovium (the lining of the joint capsule). As the inflammation progresses, the synovium becomes thick and fluid accumulation causes joint swelling and pain. A destructive pannus (new synovial tissue growth infiltrated with inflammatory cells) erodes the joint cartilage and eventually destroys the bone within the joint (Fig. 46.12). Ultimately the pannus is converted to bony tissue, resulting in loss of mobility. Joint deformity and bone loss are common in late RA (see Table 46.3).

Any connective tissue may be affected in RA, including blood vessels, nerves, kidneys, pericardium, lungs, and subcutaneous tissue. Dysfunction or failure of the organ or system can occur. Death can result if the disease does not respond to treatment.

Many patients experience spontaneous remissions and exacerbations (flare-ups) of RA. Symptoms may disappear without treatment for months or years. Then the disease flares up just as unpredictably often due to physical or emotional stress.

Etiology

Oral pathogens might be a cause of RA. Studies have shown that the symptoms of RA improve with antibiotic treatment (Ogrendik, 2013). In RA, an autoimmune response occurs that affects the synovial membrane of the joints. Antibodies (called rheumatoid factor) are often found in patients with RA. It is suggested that these antibodies join with other antibodies and form antibody complexes. These complexes lodge in synovium and other connective tissues, causing local and systemic inflammation, and may be responsible for the destructive changes of RA in body tissues.

RA affects people with a family history of the disease two to three times more often than the rest of the population.

Signs and Symptoms

Signs and symptoms vary because the disease progresses differently in patterns and rates from person to person. In general, the signs and symptoms can be divided into early and late manifestations.

The typical pattern of joint inflammation is bilateral and symmetrical. The disease usually begins in the upper extremities and progresses to other joints over many years (Fig. 46.13). Affected joints are slightly reddened, warm, swollen, stiff, and painful. The patient with RA often has morning stiffness lasting for up to an hour, and those with severe disease may report experiencing stiffness all day. Generally, activity decreases pain and stiffness.

Because of the systemic nature of RA, the patient may have a low-grade fever, malaise, depression, lymphadenopathy, weakness, fatigue, anorexia, and weight loss. As the disease worsens, major organs or body systems are affected. Joint deformities occur as a late symptom, and secondary osteoporosis (bone loss) can lead to fractures.

Several associated syndromes are seen in some patients with rheumatoid arthritis. For example, Sjögren’s syndrome is an inflammation of tear ducts (causing dry eyes) and salivary glands (causing dry mouth). Felty’s syndrome is less common and is characterized by an enlarged liver and spleen and leukopenia (decreased WBC count).
UNIT TWELVE  Understanding the Musculoskeletal System

Diagnostic Tests
No specific diagnostic test confirms RA. An increase in WBCs and platelets is typical, unless the patient has Felty’s syndrome. Immunological tests findings for patients with RA usually include the following:

• Presence of rheumatoid factor (RF) in serum
• Decreased red blood cell (RBC) count
• Decreased C4 complement
• Increased erythrocyte sedimentation rate (ESR)
• Positive antinuclear antibody (ANA) test
• Positive C-reactive protein (CRP) test.

RF can indicate the aggressiveness of the disease. However, it is not specific to RA. The ESR test screens for inflammation. It measures the amount of time it takes for RBCs to settle to the bottom of a test tube. In the presence of inflammation, RBCs settle faster in the tube. Therefore, the ESR increases with the presence of inflammation. It also evaluates the effectiveness of treatment. If the disease responds to treatment, the ESR decreases.

LEARNING TIP
Avoid shaking hands with people who have RA. A simple “Nice to meet you” or a fist bump can be more appropriate at times and will avoid the pain of even a weak handshake.

Antibiotics may improve the symptoms of RA. Chronic joint pain can interfere with mobility or the ability to perform ADLs. Drug therapy can relieve or reduce pain as well as to slow the progression of the disease. Disease-modifying antirheumatic drugs can prevent joint destruction, deformity, and disability with early single or combination drug use; NSAIDs; and corticosteroids (see Table 46.4). Many of these medications have potentially serious side effects, such as severe infection, and must be monitored carefully.

Complementary therapies that may help decrease inflammation or pain include capsaicin cream, fish oil, and antioxidants such as vitamin C, vitamin E, and beta carotene (see Chapter 5).

HEAT AND COLD. Heat applications or hot showers help decrease joint stiffness and make exercise easier for the patient. For acutely inflamed, or “hot,” joints, cold applications are preferred. A program that balances rest and exercise is most beneficial for the patient.

SURGERY. If nonsurgical approaches are not effective in relieving arthritic pain, the patient may have a total joint replacement (discussed later).

Nursing Process for the Patient With Rheumatoid Arthritis
DATA COLLECTION. A complete history and physical examination are needed for the patient with RA because the disease can involve every system of the body. In addition to assessing physical signs and symptoms, assess the patient for psychosocial, functional, and vocational needs.

After having the disease for approximately 15 years, fewer than half of RA patients are totally independent in their ADLs. These limitations may place a burden on family members, who must be included in the care of the patient with RA. Many patients with the disease are young or middle-aged. RA can impair their ability to work, depending on the type of job they have. The health care team assesses the patient’s work skills to determine the need for changes in the workplace or a need to train for a new type of work.

NURSING DIAGNOSES, PLANNING, AND IMPLEMENTATION.
Acute Pain related to chronic disease process
EXPECTED OUTCOME: The patient will report relief from pain within 30 minutes of pain relief intervention.

• Ask patient to rate pain on a scale of 0 to 10 to determine level of pain and need for pain relief.
• Provide analgesics as ordered to relieve pain.
• Ensure proper positioning and alignment to minimize discomfort and promote pain relief.
• Teach alternative measure of pain relief to maximize means to relieve pain.
• Encourage maintenance of normal weight to prevent excess wear and tear on joints.

Disturbed Body Image related to changes resulting from disease process
EXPECTED OUTCOME: The patient will come to accept alterations in body.

• Encourage patient to discuss feelings and concerns to provide the nurse with an understanding of how the patient is experiencing.
• Provide information and clarify misconceptions to ensure that the patient is aware of the expected problems and concerns.
• Encourage socialization to improve on the patient’s perceptions of how he or she “looks” to others.
• Encourage sharing with support groups so that the patient discusses his or her concerns with others experiencing the same problems.

Fatigue related to chronic pain and limited mobility
EXPECTED OUTCOME: The patient will have decreased episodes of fatigue.

• Monitor levels of fatigue throughout the day to determine the patient’s reaction to various activities.
• Ensure regular rest periods throughout the day to not overexert the patient.

X-ray examination and MRI detect joint damage and bone loss, especially in the vertebral column. A bone or joint scan assesses the extent of joint involvement throughout the body. For some patients, an arthrocentesis may be performed; the synovial fluid is cloudy, milky, or dark yellow with inflammatory cells present.

Therapeutic Measures
Antibiotics may improve the symptoms of RA. Chronic joint pain can interfere with mobility or the ability to perform ADLs. Drug therapy can relieve or reduce pain as well as to slow the progression of the disease. Disease-modifying antirheumatic drugs can prevent joint destruction, deformity, and disability with early single or combination drug use; NSAIDs; and corticosteroids (see Table 46.4). Many of these medications have potentially serious side effects, such as severe infection, and must be monitored carefully.

Complementary therapies that may help decrease inflammation or pain include capsaicin cream, fish oil, and antioxidants such as vitamin C, vitamin E, and beta carotene (see Chapter 5).

HEAT AND COLD. Heat applications or hot showers help decrease joint stiffness and make exercise easier for the patient. For acutely inflamed, or “hot,” joints, cold applications are preferred. A program that balances rest and exercise is most beneficial for the patient.
Chapter 46  Nursing Care of Patients With Musculoskeletal and Connective Tissue Disorders  

- Assist as required to minimize the amount of energy the patient needs to use.
- Teach patient the need to delegate to avoid overexertion.
- Teach energy conservation techniques to reduce workload.

Self-care Deficit related to chronic degenerative disease process
**EXPECTED OUTCOME** The patient will be able to provide own self-care.
- Observe patient’s ability to care for self to determine level of ability and adjust patient’s plan of care.
- Encourage independence to decrease feelings of despair about being unable to care for self.
- Assist when necessary to minimize frustration when patient is unable to perform self-care function.
- Teach patient about assistive devices to help with activities of daily living and promote self-care.
- Collaborate with interdisciplinary team such as home care and occupational or physical therapy to acquire assistive devices and use alternate resources.

Impaired Physical Mobility related to chronic inflammation of joints
**EXPECTED OUTCOME** The patient will have improved physical mobility.
- Administer analgesics and anti-inflammatory agents to reduce pain and increase mobility.
- Administer heat and cold therapy to aid in joint function and movement.
- Encourage continued mobilization to minimize complications of immobility.
- Collaborate with other disciplines to help with maintaining mobility.

**EVALUATION.** The outcomes are met if the patient reports pain is within acceptable levels on a pain assessment scale of 0 to 10, demonstrates acceptance of changes in body image, has decreased episodes of fatigue, is able to provide own self-care, and demonstrates improved physical mobility.

**CRITICAL THINKING**

Mrs. Harris

Mrs. Harris is a 48-year-old nurse who has had upper extremity joint pain and swelling for about 4 years. She was recently diagnosed with RA but has no systemic involvement other than extreme fatigue at this time. She is concerned that she will have to give up providing direct patient care on a busy medical unit in the local hospital.

1. What questions might the nurse ask her at this time about her illness?
2. What should the nurse discuss with Mrs. Harris about pain management?

Suggested answers are at the end of the chapter.

**PATIENT EDUCATION.** The patient with RA needs extensive patient education regarding the disease process, medication management, and the comprehensive plan of care. Encouragement with health team members, help the patient plan a daily schedule that balances rest and exercise. Child care responsibilities and other day-to-day activities need to be scheduled. A vocational counselor may be necessary for job training if the patient needs to pursue a different occupation. Patients who are unable to work may be able to qualify for disability benefits through the federal Social Security program. Inform the patient about community resources such as support groups (www.arthritis.org).

**MUSCULOSKELETAL SURGERY**

Some health problems cannot be managed conservatively and require surgery. The most common orthopedic surgeries are discussed here.

**Total Joint Replacement**

Total joint replacement (TJR) is most often performed for patients who have some type of connective tissue disease in which their joints become severely deteriorated. TJR may also be done for patients on long-term steroid therapy, such as patients with systemic lupus erythematosus (SLE) or asthma. Long-term use of steroids, trauma, and complications of joint replacement can cause avascular necrosis, a condition in which bone tissue dies (usually the femoral head) as a result of impaired blood supply. Advanced avascular necrosis is very painful and usually does not respond to conservative pain relief measures. The primary goal of TJR is to relieve severe chronic pain and improve ability to carry out ADLs when no other treatment is successful.

The most common surgeries are the total hip replacement (THR) and total knee replacement (TKR) surgeries, although any synovial joint can be replaced, including finger joints. Another term used for joint replacement is arthroplasty. The replacement devices, sometimes referred to as prostheses, are made of metal, ceramic, plastic, or a combination of these materials. Some prostheses are held in place by cement. Others are secured by the patient’s bone as it grafts and connects to the prosthesis. Bone substitutes, also called biologics, are used when the amount of available bone is insufficient to provide a good base of support for the replacement devices.

**Total Hip Replacement**

A THR uses two components: an acetabular cup that is inserted into the pelvic acetabulum and a femoral component that is inserted into the femur to replace the femoral head and neck (Fig. 46.14). A THR lasts 15 years to a lifetime.

**PREOPERATIVE CARE.** TJR is an elective procedure and scheduled far enough in advance to allow ample time for preoperative...
teaching and screening. A case manager (registered nurse or social worker) may be assigned to assess the patient’s needs and the support systems that are a viable postoperatively. It is important for the patient to have a caregiver who can assist the patient after surgery.

In addition to the normal preparations for preoperative care (see Chapter 12), the orthopedic patient requires preoperative baseline assessments. The nurse assesses the neurovascular status (circulation, sensation, mobility) of the extremity to be operated on as well as the patient’s level of pain preoperatively. Preoperative mobility is noted to assist in determining the effectiveness of the surgery. The patient is taught about the surgery and what to expect postoperatively. Some patients are scheduled to meet with the PT to learn postoperative exercises and how to ambulate with a walker or crutches.

Depending on the amount of blood loss during surgery, some patients receive postoperative blood transfusions. Because TJR is an elective procedure, the HCP may order autologous blood donation by the patient. The patient donates blood before surgery per guidelines (e.g., time frames specific, hemoglobin levels normal), which is then available for reinfusion postoperatively as needed. This predeposited blood donation is cost-effective and reassures patients who are concerned about receiving blood from other donors.

Patients are often admitted to the hospital the morning of surgery. A prophylactic antibiotic preoperatively is given just before surgery to minimize the chance of an infection (especially osteomyelitis) developing. The patient’s length of stay varies but is about 2 to 5 days, depending on the patient’s age and progress. Some hospitals use joint camp programs where a group of patients undergoing joint replacements are admitted on the same day, undergo their surgery, and then recover together during activities such as physical therapy with each other for support.

**POSTOPERATIVE CARE.** Care for the patient having a total hip replacement is interdisciplinary. The patient usually gets out of bed and into a chair the night of surgery or early the next day. Ensure that the patient does not adduct or hyperflex the surgical hip during transfer to the chair. The chair should have a straight back and be high enough to prevent excessive flexion. The toilet seat should also be raised for the same purpose. Permitted amounts of weight bearing depend on the type of prosthesis used. In general, weight bearing as tolerated or full weight bearing is used for cemented prostheses. If an uncemented device is used, the patient may be restricted to toe-touch, partial weight bearing, or featherweight bearing.

Because patients undergoing total hip replacement are in chronic pain preoperatively, some patients report that they have less pain postoperatively than they had before surgery. Initially, pain typically is managed by epidural analgesia, patient-controlled analgesia (PCA), or injections with analgesics. After the first postoperative day, the patient usually progresses to an oral analgesic.

Early ambulation helps prevent postoperative complications such as atelectasis and deep vein thrombosis (DVT). The PT works with the patient for ambulation, a walker or crutches. After 4 to 6 weeks, the patient progresses to a cane. The patient does not need an ambulatory device if there is no limping.

Because of restrictions in hip flexion, patients are instructed not to bend forward to tie shoes or put on pants. The OT provides adaptive or assistive devices, such as dressing sticks and long-handled shoe horns, to assist the patient in being independent in ADLs.

In addition to providing the general postoperative care that all patients undergoing general or epidural anesthesia require, plan and implement interventions to help prevent the following common complications of THR (see Chapter 12).

**Hip Dislocation.** The most common postoperative complication for the patient having a total hip replacement is subluxation (partial dislocation) or total dislocation. Dislocation occurs when the femoral component becomes dislodged from the acetabular cup. Often, if a dislocation occurs, there is an audible “pop” followed by immediate pain in the affected hip. In addition to pain, the patient experiences shortening of the surgical leg and possibly internal rotation of the surgical leg. If any of these signs and symptoms occur, notify the surgeon immediately and keep the patient in bed. Additional analgesics may be ordered until the patient can be taken to the operating room. Under anesthesia, the surgeon manually manipulates the hip back into alignment and immobilizes the leg until healing occurs.

**Prevention of dislocation** is a major nursing responsibility. Correct positioning of the surgical leg is critical. The primary goals are to prevent hip adduction (across the body’s midline) and hyperflexion (bending forward more than 90 degrees). To accomplish these goals, place the patient returning from the perianesthesia care unit (PACU) in a supine position with the head slightly elevated. A trapezoid-shaped abduction pillow (sometimes called a triangular pillow), splint, wedge, or regular bed pillows may be placed between the legs to prevent adduction. The patient can be turned to the side specified by the HCP (even the operative side if the patient is comfortable enough), with hip adduction avoided. The patient is turned with the...
abductor pillow or three regular pillows (one proximal and two distal) in place between the legs. When turning, it is important to turn the hip and legs simultaneously to minimize the chance of dislocation. Support for the leg and abductor pillow is also required when the patient is turned on his or her side to decrease the chance of dislocation.

To prevent hyperflexion, some surgeons initially allow the patient to sit at no more than a 60-degree angle in a reclining chair. The patient’s position is progressed to 90 degrees, the maximum allowed to prevent hyperflexion (Fig. 46.15). While the patient is on bedrest, the use of a fracture bedpan is recommended when helping the patient with toileting needs to minimize discomfort and to prevent the possibility of dislocation.

**Skin Breakdown.** Because most patients having total joint replacements are older, skin breakdown prevention is a major part of postoperative care. Turning the patient at least every 2 hours (more often if high risk) and keeping the heels off the bed help prevent pressure ulcers. Heels, elbows, and the sacrum are vulnerable and can break down in 24 hours. A reddened area that does not blanch is a stage 1 pressure ulcer and must be treated aggressively to prevent progression to other stages. Prophylactic application of cushioning dressings and the use of heel protectors help to decrease the chance of skin breakdown of the heels.

Patients who are incontinent must be kept clean and dry. Assisting the patient to use the toilet every 2 hours and using a protective barrier cream also help prevent skin problems related to incontinence. Adequate diet and hydration are also important to prevent skin breakdown. Box 46-5 describes additional nursing interventions that meet the needs of postoperative patients recovering from THR.

**Infection.** Orthopedic surgery patients are at an increased risk for infection because of the nature of the surgery and age. In addition to a preoperative prophylactic IV antibiotic, the surgeon can irrigate the incision with antibiotics intraoperatively, place antibiotic beads in the incision, or continue IV antibiotics for 24 hours postoperatively.

Depending on institution policies, the surgeon may be the one who removes the initial dressing. Regardless of who removes the dressing, meticulous aseptic care of the surgical wound is important to minimize the chance of infection. Care of the incision, as well as exit sites for drains, is performed aseptically. When performing dressing changes, observe the incision for signs and symptoms of infection (redness, swelling, warmth, odor, pain, or yellow, green, or brown-tinted drainage). Monitor temperature. An older patient with an infection might not experience a fever, but may exhibit confusion due to the infection.

Infection may not occur during the patient’s hospital stay but can occur 1 or more years later. If this late infection does not respond to antibiotics, the prosthesis may be removed and replaced.

---

**Box 46-5 Nursing Interventions Following Total Hip Replacement**

- Ensure the hip is not allowed to become adducted. Can use abductor pillow or pillows.
- Turning patient requires abduction to be maintained. Turn patient as a whole, not allowing hip or legs to fall forward or backward. Use pillows to support raised limb.
- Monitor for skin integrity of the opposite heel, which often is used to help mobilize in bed and so is prone to friction and pressure sores. Apply protective devices for heels.
- Make sure limb remains in abduction when moving patient out of bed.
- Prevent postoperative pneumonia by encouraging deep breathing and coughing and use of incentive spirometer.
- Pain control is of utmost importance. Provide regularly scheduled analgesics, and make sure breakthrough analgesia is provided as needed.Decreased pain allows for earlier mobilization and fewer complications of immobility.
- Monitor level of consciousness and orientation. Many older patients have alterations in mental status after surgery because of anesthetics, analgesics, blood loss, and environmental changes.

**CRITICAL THINKING**

Mrs. Adam

Mrs. Adam is 78 years old and had a left total hip replacement 3 days ago. When changing her dressing, the nurse notices a purulent discharge. Cefaclor (Cefclor) 500 mg by mouth every 8 hours is ordered. It is available as a 375-mg/5-mL suspension. How many milliliters should Mrs. Adam be given?

Suggested answers are at the end of the chapter.
Bleeding. In TJR, up to two-thirds of any blood loss can occur postoperatively. The patient might have a surgical drain (e.g., Hemovac or Jackson-Pratt) that is emptied every 8 to 12 hours as ordered for the first day or two, although the use of drains has decreased to prevent infection. Monitor dressings for drainage and report large or unexpected amounts. Reinforce it as needed. On the second or third postoperative day, the patient’s hemoglobin and hematocrit may decrease to the point that blood transfusion is needed. The patient might receive autologous blood or salvaged operative or postoperative blood. By using an orthopedic patient autotransfusion (such as OrthoPAT®) during surgery, about 50% of blood that is lost can be recovered and saved for reinfusion into the same patient. Postoperatively, blood can be replaced by collecting shed blood via suction into a reservoir, then filtering and reinfusing it within 6 hours of collection. Monitoring for blood loss and signs of shock is an important nursing action.

Neurovascular Compromise. For any musculoskeletal surgery or injury, frequent neurovascular checks for circulation (color, warmth, pulses), sensation, and movement are performed distal to the surgical procedure or injury (and compared with the unaffected side) when vital signs are checked. The procedure and significance of these assessments are described in Chapter 45.

Venous Thromboembolitic Complications. Patients having hip surgery are at the greatest risk for DVT or pulmonary embolus. Older adult patients, obese patients and those with a history of thromboembolic problems are also at a high risk for potentially fatal problems. Thigh-high elastic stockings and intermittent pneumatic compression devices may be used while the patient is hospitalized (see Chapter 12). Anticoagulant medication is given to help prevent clot formation.

Total Knee Replacement

The knee is the second most commonly replaced joint. It requires three components for total replacement: a femoral component, a tibial component, and a patellar button (Fig. 46.16).

Box 46-6 Patient Education After Total Hip Replacement

Follow these safety measures to prevent hip dislocation:
• Keep legs abducted (away from center of body) with pillows.
• Sleep with pillows between legs until HCP states otherwise.
• Bend at the waist (hip) no more than 90 degrees.
• Get up from a sitting position by pushing straight up off of the chair or bed without leaning forward.
• Use a walker, if desired, to assist walking.
• Physiotherapy and occupational therapy can provide equipment that aids in putting on socks and shoes.
• Sexual activity can be started when tolerated, provided hip safety measures are followed.
For patients who do not yet need a total replacement, partial knee resurfacing is available.

Care for the patient with a TKR is similar to that required for a patient with a hip replacement except that dislocation, and therefore preventive positioning, are not a concern. Postoperatively, a bulky dressing and possibly a surgical drain are in place. Once again, it is important to monitor for bleeding along with the usual postoperative interventions. Medical complications described for THR, such as DVT, may be seen in the patient undergoing knee replacement (see Box 46-5).

**Amputation**

An amputation is the removal of a body part, which can be as limited as removing part of a finger or as devastating as removing nearly half the body. Amputations may be *surgical* as a result of disease or *traumatic* as a result of an accident.

**Surgical Amputation**

The main indication for surgical amputations is ischemia from peripheral vascular disease (PVD) in the older adult. The rate of lower extremity amputation is much higher in the diabetic patient than in the nondiabetic patient (see diabetes in Chapter 40). Surgical amputations may also be done for bone tumors, thermal injuries (frostbite, electric shock), crushing injuries, congenital problems, or infections.

**Traumatic Amputation**

Traumatic amputations occur from accidents, often in young and middle-aged adults. Industrial machinery, motor vehicles, lawn mowers, chain saws, and snow blowers are common causes of accidental amputation.

Because in these patients the amputated part is usually healthy, attempts at *replantation* can occur. One of the most common replantations is one or more fingers. Prehospital care of the severed body part includes rinsing if dirty and wrapping in a clean, moist cloth that is placed in a sealed plastic bag. The bag should then be placed into ice cold water until the body part is transported to the hospital. The surgical procedure is performed by specialists who operate using a microscope. Nerves, vessels, and muscle must be reattached.

**Levels of Amputation**

The most common surgical amputation site is the lower extremity. The loss of the great toe affects balance and gait. Midfoot amputations are preferred over below-the-knee amputations for patients with peripheral vascular disease. The more proximal the amputation, the more disability is present.

If the lower leg is amputated, a below-the-knee amputation is preferred over an above-the-knee amputation to preserve joint function. The higher the level of amputation, the more energy required for ambulation. Hip disarticulation (removal through the hip joint) and *hemipelvectomy* (removal through part of the pelvis) are reserved for young patients who have cancer or severe trauma. Rarely, a hemipcordectomy (hemipelvectomy plus a transumbar amputation) is performed as a last resort for young patients with cancer. This radical surgery removes nearly half of the body and requires both bowel and urinary diversion surgeries (ostomies) as well.

Upper extremity amputations are usually more significant than lower extremity amputations and more often result from trauma. The arms and hands are necessary for performing ADLs. Early replacement with a prosthesis is crucial for the patient with an upper extremity amputation.

**Preoperative Care**

Patients who are scheduled for elective amputations have the advantage of time for preoperative teaching, prosthesis fitting, and adjustment to the loss of part of their bodies. Preoperative teaching is started in the surgeon’s office. Postoperative and rehabilitative care is re viewed with the patient and family or significant other. Those patients experiencing a traumatic amputation have no opportunity to prepare for the significant changes that will result from the accident. Preoperative care will not only involve physical needs being met, but significant psychological and emotional concerns also have to be addressed (this also continues postoperatively).

Preoperatively, the patient should be referred to a certified prosthetist-orthotist to begin plans for replacing the removed body part with a prosthesis.

**Disturbed Body Image** is a common nursing diagnosis for the patient having an amputation. If possible, it is helpful for the preoperative patient to meet with a rehabilitated amputee. Assess the patient’s reaction to having an amputation with the expectation that the patient will experience many of the stages of loss and grieving. Support systems and coping mechanisms are identified that can help the patient through the surgery and postoperative period. Ensure that appropriate support is provided by other disciplines such as social work and clergy.

**Postoperative Care**

In addition to the general postoperative care described here, plan and implement interventions to help prevent postoperative complications, including hemorrhage and infection (see Chapter 12).

**PREVENTION OF HEMORRHAGE AND INFECTION.** When a patient loses part of the body, because of either surgery or trauma, blood vessels are severed or damaged. The patient returns from surgery with a large pressure dressing that is secured with an elastic wrap. Assess the closest proximal pulse between the heart and the amputated body part for strength and compare findings with the nonsurgical extremity. Assess the bulky dressing for bloody drainage. If blood is on the dressing when the patient is admitted to the PACU or the surgical unit, circle, date, and time the area of drainage and closely monitor for enlargement. If bleeding continues, the surgeon is notified immediately. A tourniquet should be readily available in case severe hemorrhage occurs.

After the dressing is removed, observe for adequate perfusion to the skin flap at the end of the residual limb, referred to as the stump. The skin should be pink in a light-skinned

---

**WORD BUILDING**

replantation: *re—again + plant—to plant + ation—process*

hemipelvectomy: *hemi—half + pelv—pelvis + ectomy—removal of*
patient and not discolored (lighter or darker than other skin pigmentation) in a dark-skinned patient. The residual limb temperature to touch should be warm but not hot.

Infection of the wound can be problematic, especially if the infection enters the bone (osteomyelitis). Inspect the wound for intense redness or drainage. Localized infections usually do not cause an increase in body temperature. If temperature is elevated, it could indicate a serious wound infection, a systemic infection, or some other type of infection. Traumatic amputations are at risk for developing infection due to the nature of the injury and the likelihood of exposure to environmental pathogens from the source of the amputation.

**PAIN CONTROL.** Phantom pain arises from the spinal cord and brain. The patient reports severe pain usually distal to the removed body part. The pain may be described as intense burning, cramping, shooting, stabbing, or throbbing. Phantom pain can be triggered by touching the residual limb, fatigue, emotional stress, or weather changes. It can improve over time.

Never doubt that a patient is experiencing phantom pain. Phantom sensation is different from phantom pain in that the patient feels as if the limb is still present rather than being painful. Treat phantom pain with prescribed medication and complementary and alternative therapies. Medications used include anticonvulsants, such as gabapentin (Gralise, Neurontin) or pregabalin (Lyrica), beta-blocking agents, such as propranolol (Inderal), and antidepressants like amitriptyline (Elavil). To complement traditional therapy, a number of alternative therapies may be useful, including biofeedback, nerve stimulation, myoelectric prosthesis, massage, mirror box (watch unaffected limb while moving), imagery, acupuncture, spinal cord or brain stimulation (small electric current used). Future therapy involves virtual reality goggles (appears as if no amputation occurred).

**MOBILITY AND AMBULATION.** To reduce surgical swelling, cold application may be ordered. Alternatively, the residual limb may be elevated on a pillow for 24 hours or less. Continued use of a pillow for elevation can lead to flexion contractures, especially for patients with a below-the-knee or above-the-knee amputation. If the hip becomes contracted, using a prosthesis will not be possible because the patient will not be able to walk. Check the limb periodically to ensure that it lies completely flat on the bed. The patient should avoid positions of flexion such as sitting for long periods. If the patient is able, lying prone (on the stomach) for 30 minutes four times daily helps prevent hip contracture (abnormal shortening of muscle or scar tissue).

Postoperative care after amputation is interdisciplinary, often requiring an extensive rehabilitation program in a subacute unit, an extended care facility, or on an ambulatory basis. The PT teaches the patient muscle-strengthening exercises that help with ambulation and transfers and prevent flexion contractures. A trapeze bar on an overhead bed frame aids in strengthening the arms and helps the patient move around in bed.

**PROSTHESIS CARE.** The residual limb must be prepared for wearing the prosthesis. A temporary prosthesis may be worn until the swelling subsides.

The residual limb is wrapped at least every 8 hours using an elastic wrap (such as an Ace wrap) in a figure-of-eight fashion (Fig. 46.17). It is important to perform neurovascular checks and assess the residual limb for infection and alterations in tissue integrity at each rewrapping. Begin with the most distal portion and proceed proximally until the bandage is secured to the most proximal joint. The bandage should be tighter at the distal end.

The prosthesis requires special care, which the patient should be taught:

- Clean the prosthesis socket with mild soap and water and then dry it.
- Clean inserts and liners regularly.
- Use garters to keep socks in place.
- Grease parts as instructed.
- Replace shoes when they wear out, with same height and type of shoe.

**LIFESTYLE ADAPTATION.** The patient may feel that life will be markedly changed as a result of the amputation. If the case manager thinks it is needed, a job analysis may be conducted by a vocational analyst or specialized case manager. With technological advances in prostheses, most patients who worked before surgery are able to return to their jobs after surgery. Many patients with amputations are able to bowl, ski, hike, and continue with all of the recreational hobbies that were able to do before surgery.

A supportive family or significant other is vital to help the patient adjust to body image change. Consider the need for a sexual counselor or psychologist if indicated. For any patient with an amputation, help the patient set realistic expectations.

For the patient who is not a candidate for a prosthesis, home adaptations for a wheelchair may be needed. The patient must have access to toilet facilities and areas necessary for self-care. Structural changes in the living environment may be needed before the patient can be discharged from rehabilitation.

**FIGURE 46.17** Application of elastic wraps on an above-the-knee amputation helps mold the stump for a prosthesis.
Chapter 46  Nursing Care of Patients With Musculoskeletal and Connective Tissue Disorders  1091

Home Health Hints

- If equipment or modifications to the home are needed following hospitalization for an orthopedic adaptation, it is best if they can be arranged or obtained before discharge.
- Physical and/or occupational therapy are often ordered for the orthopedic patient discharged from the hospital to help with ambulation, ADLs, and obtaining and use of assistive devices: raised toilet seats, handheld reachers, walkers, canes, wheelchairs, and hand rails.
- Physical and/or occupational therapy can also be ordered to help the patient regain strength following surgery. The home health nurse can work with the therapist to educate the patient on the prescribed exercises.
- Patients who use walkers can get pressure ulcers on their palms. One way to relieve the pressure is to wear padded cycling gloves that leave the fingers free.
- A patient on crutches can use the crutch to prop a casted leg or foot.
- Research has shown that pain or fear of falling may prevent a patient from moving and functioning to maximum potential. Encourage patients to wear flat, sturdy, rubber-soled shoes to prevent slipping, tripping, or turning an ankle.
- Encourage the patient to remove all throw rugs, unnecessary furniture, and other possible fall hazards in the home.
- The risk of DVT after hip or knee surgery is highest by the fifth postoperative day, and the risk persists for up to 12 weeks. Be alert for such signs as warmth, redness, edema, positive Homans’ sign, and protective behavior of the affected leg.
- Patients who are having a difficult time putting on compression stockings can be shown how to slip them on easily. Using a plastic grocery bag, instruct the patient to tie a knot on the closed end. Slip the bag over the foot, and then put the stocking on over the bag. Once the stocking is on over the heel, the patient or caregiver can pull the bag out using the knot that was tied.
- Aids are available for putting on compression stockings such as the Doff N’ Donner, a rubberized device filled with water, that slides up the leg unrolling the stocking in place (www.doffanddonner.com).
- Many times the patient is discharged home still requiring medication injections to prevent DVT formation. The nurse will educate the patient on how to administer the injection. If the patient cannot do this and no one is available to teach him or her, the home health nurse can make visits to administer the injection.
- Instruct the patient with rheumatoid arthritis to rest during acute inflammations and to stop activity if pain develops.
- Home health nurses frequently remove staples and sutures. Always have several of each type of removal device on hand. Remember staples, scissors, or other items that are “sharp” need to be disposed of in a biohazard container.

SUGGESTED ANSWERS TO

CRITICAL THINKING

Mrs. Martinez

1. When documenting, answer the questions what, why, where, who, and how to make the charting complete.

   What = Patient found on the floor on her left side, moaning and holding her left leg, crying out with any movement.

   Why = fall

   When = Date/Time: 1000

   Where = day room

   Who = Mrs. Martinez (patient)

   How = unknown, was not witnessed.

   Date: 1000. Found on floor in day room lying on left side, moaning and holding left leg, crying out with any movement. Stated, “I fell. I think my leg is broken.” Supervisor immediately notified paramedics and Dr. Haas notified. BP 150/84, P 100, R 20. Left leg shorter than right. Remained with patient and instructed not to move until paramedics arrived. Blankets applied and pillow under head. Taken to Memorial Hospital by ambulance at 1000. I. Smith, LPN

2. A. Risk for vascular trauma related to possible hip fracture.

   B. Pain, related to fall, as evidenced by patient moaning and holding her leg, crying with movement.

   C. Fear related to pain at left hip as evidenced by anxiety.

Continued
Frank Schnell

1. Possible priority nursing diagnoses include:
   a. Pain related to injury and immobility
   b. Risk for constipation related to opioids and immobility
   c. Risk for Impaired Skin Integrity related to extended recovery time
   d. Risk for Social Isolation related to hospitalization
   e. Deficient Diversional Activity related to extended need for bedrest

2. Nursing interventions may include:
   a. Monitor pain level, provide analgesics as ordered, check pain relief. Check position for comfort. Provide backrubs prn.
   b. Ensure Frank’s diet includes fiber and adequate hydration (1.5–2 L/day); give stool softener as ordered; monitor daily bowel movements.
   c. Ensure Frank does the exercises recommended by occupational and physical therapists; reposition him every 2 to 3 hours; have trapeze bar set up for Frank to use; use skin assessment tool to determine risk for skin breakdown; check for pressure points and signs and symptoms of skin breakdown.
   d. Encourage Frank’s family and friends to alternate visits; have an occupational therapist assess Frank’s social needs.
   e. Encourage Frank to listen to music; encourage visitors; and ensure access to hobbies, videos, books, magazines, and comics.

Mr. Finn

1. a. “What is your typical day on the job like?”
   b. “Do certain activities increase joint pain?”
   c. “When is your pain worse, after activity or after rest?”
   d. “How long have you experienced joint pain?”
   e. “What relieves the joint pain?”

2. Risk factors include that he is overweight, is in late middle age, and has a physically demanding job.

3. Other signs and symptoms may include bony nodules on his fingers (such as Heberden’s nodes) and secondary inflammation causing joint swelling.

4. Pain management, weight loss, restoring and maintaining functional ability: bending ability for work.

5. HCP, pharmacist, nurse, physical therapist, occupational therapist.

Mrs. Harris

1. Ask:
   a. The nature of her pain
   b. If it is worse after activity or rest
   c. If she experiences joint stiffness and, if so, when. Follow the WHAT’S UP? method of pain assessment.

2. Teach the following:
   a. Balance rest with exercise.
   b. Use ice for very hot, swollen joints.
   c. Use heat to decrease stiffness.

Mrs. Adam

Unit analysis method:

\[
\frac{500 \, \text{mg}}{5 \, \text{mL}} = \frac{375 \, \text{mg}}{x \, \text{mL}}
\]

\[
x = \frac{375 \times 5}{500} = \frac{1875}{500} = 3.75 \times 2 = 6.75 \, \text{mL}
\]
Chapter 46  Nursing Care of Patients With Musculoskeletal and Connective Tissue Disorders

REVIEW QUESTIONS

1. The nurse is caring for a patient being transferred into bed who has just had a plaster long-leg cast applied and reports pain of 6 on a scale of 0 to 10. Place the nursing interventions in order of priority.
   1. Expose cast to air dry.
   2. Administer ordered analgesic.
   3. Check circulation, sensory, and mobility status.
   4. Palm cast while position on pillow.
   5. Obtain vital signs.

2. The nurse is caring for a patient with an external fixation device. Which of the following actions should the nurse implement? Select all that apply.
   1. Avoid touching the pins.
   2. Follow agency protocol for pin care.
   3. Cleanse pins with hydrogen peroxide four times daily.
   4. Loosen screws holding the pins during cleaning.
   5. Monitor pin insertion sites daily.

3. The nurse is caring for a patient with an open fracture. Which of the following actions are essential for the nurse to perform to help prevent osteomyelitis? Select all that apply.
   1. Perform hand hygiene before dressing change.
   2. Wear a protective gown.
   3. Wear a mask.
   4. Wear goggles.
   5. Wear sterile gloves to apply new dressing.

4. The nurse is caring for a patient who is postmenopausal, has osteoporosis, lost 2 inches of height, is thin, and has never exercised regularly. Which of these interventions should be included in the plan of care to prevent further bone loss?
   1. Decrease participation in activities of daily living.
   2. Avoid weight-bearing activities.
   3. Encourage regular exercise.
   4. Encourage weight gain.

5. The nurse is contributing to the plan of care for a patient with Paget’s disease. Which of these is a priority nursing diagnosis for this patient?
   1. Pain
   2. Deficient Knowledge
   3. Excess Fluid Volume
   4. Deficient Fluid Volume

6. The nurse is caring for a male patient with gout. Which of the following lab values would the nurse expect in this patient?
   1. White blood cell count 6.2 cells/mL
   2. Potassium 5 mEq/L
   3. Uric acid 10.2 mg/dL
   4. Ammonia 34 μmol/L

7. A patient with osteoarthritis who had a right total knee replacement tells the nurse that the other knee is becoming painful. Which of the following is the most appropriate instruction to help the patient preserve function of the left knee?
   1. Reduce dietary purines.
   3. Maintain normal uric acid levels.
   4. Begin a jogging program.

8. A patient is scheduled for a right total hip replacement. The nurse should teach which of the following postoperative leg positions?
   1. Maintain legs in adduction.
   2. Maintain legs in abduction.
   3. Maintain internal leg rotation.
   4. Maintain more than 90-degree hip flexion.

9. The nurse is caring for a patient immediately after a below-the-knee amputation. Which of these assessments should the nurse consider a PRIORITY?
   1. Sacral edema
   2. Mobility
   3. Stump dressings
   4. Blood sugar level

10. The nurse is collecting and reviewing data on a patient with a left tibia fracture. Which of the following findings would indicate a complication of this fracture?
    1. Increased red blood cell count.
    2. Decreased body temperature.
    3. Decreased lymphocyte count.
    4. Absent left pedal pulse.
11. A patient who has a 36-hour-old fractured femur had morphine 5 mg intramuscularly 1 hour ago and is now reporting severe unrelieved pain. Which nursing action is most appropriate?
   1. Administer an analgesic.
   2. Apply Buck’s traction.
   3. Reposition with head of bed up.
   4. Notify the health care provider.

12. A patient who had a total knee replacement is to receive Toradol 15 mg intramuscularly every 6 hours as needed for pain. The Toradol comes as 30 mg/mL. How many milliliters should the nurse give?
   Answer: ________ mL

LEARNING OUTCOMES

1. Describe the normal structures and functions of the nervous system.
2. Identify the effects of aging on the nervous system.
3. List data to collect when caring for a patient with a disorder of the nervous system.
4. Identify tests used to diagnose disorders of the nervous system.
5. Plan nursing care for patients undergoing each of the diagnostic tests for disorders of the nervous system.
6. Describe common therapeutic measures that are used for patients with disorders of the nervous system.
NORMAL NEUROLOGIC SYSTEM ANATOMY AND PHYSIOLOGY

The nervous system has two divisions: the central nervous system (CNS), which consists of the brain and spinal cord, and the peripheral nervous system (PNS), which includes the nerves of the autonomic nervous system (ANS). Electrical impulses are transmitted through the nervous system to permit sensory, motor, and integrative activity. Actions are either automatic by reflex or a result of gathering, organizing, and processing data.

Nerve Tissue

Nerve tissue consists of neurons and support cells called neuroglia (Table 47.1). There is diversity in neurons; including unipolar, bipolar, and multipolar anatomy. Most common is the multipolar neuron with multiple dendrites and a singular axon (Fig. 47.1).

Myelination of axons increases their conduction speed. The level of myelination correlates to the necessity of speed. For example, neurons involved in protective reflexes are heavily myelinated, whereas processing neurons of the CNS lack myelin.

Types of Neurons

Functional classification of neurons considers their position and direction of signal: a neuron is sensory (afferent), motor (efferent), or an interneuron (between the afferent and efferent neurons, Fig. 47.2). Receptors are specialized to detect external or internal changes and then generate electrical impulses.

Sensory neurons, from receptors in the skin, skeletal muscles, and joints, are called somatic. Those sensory neurons from receptors in internal organs are called visceral sensory neurons. Motor neurons that innervate skeletal muscle are called somatic; those to smooth muscle, cardiac muscle, and glands are called visceral.

LEARNING TIP

To remember the difference between afferent and efferent, try these clues:

- Afferent: A is for affect or sense.
- Efferent: E is for effect (action).
- Or, think of the alphabet—A before E: You have to feel or sense (afferent) a stimulus before you can take action (efferent).

Nerve Impulses

A nerve impulse, which is also called an action potential, is an electrical change brought about by the movement of ions across the neuron cell membrane. When a neuron is at rest, it is polarized with a positive charge outside the membrane and a relatively negative charge inside the membrane. A threshold stimulus will cause a reversal in charge (action potential). A wave of depolarization travels the length of the neuron as a positive feedback loop. Immediately after is repolarization, restoring the positive charge outside and the negative charge inside. After a refractory period (the brief time after being stimulated when a nerve still can’t react to another stimulus), the neuron is polarized again and ready to respond to another stimulus. A myelinated neuron is capable of transmitting hundreds of impulses per second and at speeds of more than 100 meters per second.

Synapses

Neurons typically work in a circuit. When the axon of a neuron must transmit an impulse to the dendrite or cell body of another neuron, the impulse must cross a small gap called a synapse. An electrical impulse is incapable of crossing this microscopic space, so when an impulse reaches the synapse, impulse transmission becomes chemical.

At chemical synapses, impulse transmission is one way because the neurotransmitter is released only by the presynaptic neuron; the impulse cannot go backward. This is important for the normal activity of functional neurons. The relative complexity of synapses also makes them a potential target for the actions of medications. For example, some antidepressants block the reuptake (reabsorption) of serotonin, a neurotransmitter, back into the proximal nerve endings, increasing the mood-elevating serotonin levels in the synapse.
The cell body (also called the soma) is the control center of the neuron and contains the nucleus.

Dendrites, which look like the bare branches of a tree, receive signals from other neurons and conduct the information to the cell body. Some neurons have only one dendrite; others have thousands.

The axon, which carries nerve signals away from the body, is longer than the dendrites and contains few branches. Nerve cells have only one axon; however, the length of the fiber can range from a few millimeters to as much as a meter.

The axons of many (but not all) neurons are encased in a myelin sheath. Consisting mostly of lipid, myelin acts to insulate the axon. In the peripheral nervous system, Schwann cells form the myelin sheath. In the CNS, oligodendrocytes assume this role.

Gaps in the myelin sheath, called nodes of Ranvier, occur at evenly spaced intervals.

The end of the axon branches extensively, with each axon terminal ending in a synaptic knob. Within the synaptic knobs are vesicles containing a neurotransmitter.

Sensory (afferent) neurons detect stimuli—such as touch, pressure, heat, cold, or chemicals—and then transmit information about the stimuli to the CNS.

Interneurons, which are found only in the CNS, connect the incoming sensory pathways with the outgoing motor pathways. Besides receiving, processing, and storing information, the connections made by these neurons make each of us unique in how we think, feel, and act.

Motor (efferent) neurons relay messages from the brain (which the brain emits in response to stimuli) to the muscle or gland cells.

Nerves and Nerve Tracts

A nerve (whether cranial, spinal, or peripheral) is a group of axons with blood vessels, wrapped in connective tissue. Most nerves are mixed; that is, they contain both sensory and motor neurons. Some, however, are not mixed. For example, the optic nerve for vision is sensory only; and the autonomic nerves are purely motor.

A nerve tract is a group of thickly myelinated neurons within the CNS; such tracts within white matter appear white due to the myelin sheaths. A nerve tract within the spinal cord carries either sensory or motor impulses; those within the brain may have sensory, motor, or integrative functions.

Spinal Cord

The spinal cord transmits impulses to and from the brain and is the integrating center for spinal cord reflexes. The spinal cord is within the vertebral canal formed by the vertebrae of the skeleton and extends from the foramen magnum of the occipital bone to the intervertebral disk between the first and second lumbar vertebrae. The spinal nerves emerge from the intervertebral foramina.

In cross-section, the spinal cord is oval shaped; internally it has an H-shaped mass of gray matter surrounded by white matter (Fig. 47.3). Each spinal nerve attaches to the cord by two roots: dorsal and ventral. Meninges (three concentric, external layers of connective tissue) and circulating cerebrospinal fluid (CSF) offer further protection to the spinal cord.

Spinal Nerves

There are 31 pairs of spinal nerves, named according to their respective vertebrae: 8 cervical pairs, 12 thoracic pairs, 5 lumbar pairs, 5 sacral pairs, and 1 coccygeal pair. These nerves are often referred to by letter and number: the second cervical nerve is C2, the tenth thoracic is T10, and so on (Fig. 47.4).

Spinal Cord Reflexes

A reflex is a fast, involuntary, automatic, and predictable response to a stimulus. A spinal cord reflex uses a neural circuit, independent of the brain, called a spinal reflex arc. Sensory input elicits motor output (Fig. 47.5).

The somatic spinal cord reflexes include stretch reflexes and flexor reflexes. In a stretch reflex, a muscle that is stretched automatically contracts; an example is the familiar patellar reflex, but all skeletal muscles have such a reflex. Because gravity exerts a constant force on the body, the purpose of these reflexes is to keep the body upright without requiring conscious processing. They also avoid potential injury from overstretching a muscle. Flexor reflexes may also be called withdrawal reflexes: the stimulus is painful trauma to tissue and the response is to pull away from it. Again, this occurs without the need for conscious thought; the brain is not directly involved.

The clinical testing of spinal cord reflexes provides a way to assess the functioning of their reflex arcs. For example, if the patellar reflex is absent, the problem might be in the quadriceps femoris muscle, the femoral nerve, or the spinal cord itself. If the reflex is present, it indicates that all parts of the reflex arc are functioning normally.

Brain

The brain consists of many parts that function as an integrated whole. The four principle areas are the cerebrum, the diencephalon (thalamus and hypothalamus), the brainstem (midbrain, pons, and medulla oblongata), and the cerebellum (Fig. 47.6).

Meninges

The meninges are the three layers of connective tissue that cover the CNS. Where they enclose the brain, they are referred to as cranial meninges.
1. Somatic receptors (located in the skin, a muscle, or a tendon) detect a sensation, such as the stretching of the thigh muscle when the patellar tendon is tapped.

2. Afferent (sensory) nerve fibers send a signal directly to the spinal cord.

3. The impulse immediately passes to a motor neuron.

4. The motor neuron initiates an impulse back to the muscle, causing it to contract, producing a slight kick in the lower leg.

Ventricles and Cerebrospinal Fluid

The ventricles are four cavities within the brain: two lateral ventricles are located within the cerebral hemispheres, the third ventricle lies midline within the thalamus, and the fourth ventricle is midline between the brainstem and cerebellum. Cerebrospinal fluid is formed from capillaries of the choroid plexus within, and circulates through the four ventricles. Circulation of CSF moves inferiorly within the CNS, into the subarachnoid space, and ultimately superiorly to drain into the dural venous sinuses. Cerebrospinal fluid permits the exchanges of nutrients and wastes between the blood and CNS neurons. It also acts as a cushion or shock absorber for the CNS. The pressure and constituents of CSF may be determined by means of a lumbar puncture (spinal tap) and may be helpful in the diagnosis of diseases such as meningitis.

Brainstem: Midbrain, Pons, and Medulla Oblongata

Primarily a reflex center, the midbrain regulates visual reflexes (coordinated movement of the eyes), auditory reflexes (turning the ear toward a sound), and righting reflexes that keep the head upright and contribute to balance. Within the pons are two respiratory centers that work with those in the medulla to produce a normal breathing rhythm. The medulla lies just superior to the spinal cord. It regulates the most vital life functions.

Cerebellum

The cerebellum is posterior to the brainstem. The functions of the cerebellum include the involuntary aspects of voluntary movement: coordination, appropriate direction and endpoint of movements, and the maintenance of posture and balance. For the maintenance of balance, the cerebellum uses input from vision, proprioceptors, and equilibrium receptors in the inner ear to detect movement and changes in position.

Diencephalon: Thalamus and Hypothalamus

Deep beneath the cerebral hemispheres, the diencephalon consists primarily of the thalamus and hypothalamus. Above the brainstem, the thalamus acts as a gateway for nearly every sensation traveling to the cerebral cortex. The thalamus filters sensory input, permitting the cerebrum to concentrate on more important sensations with less distraction. The hypothalamus suspends the pituitary gland from a stalk called the infundibulum; they are anatomically and physiologically connected.

Cerebrum

The two cerebral hemispheres form the largest part of the human brain. The right and left hemispheres are connected primarily by the corpus callosum, a band of about 300 million nerve fibers. The cerebral cortex is folded extensively into convolutions (or gyri) that create a surface area for neurons. The deep grooves between the folds are called fissures; shallow grooves are called sulci. The cerebral cortex is divided into lobes, whose functions have been extensively mapped (Fig. 47.7).

Collectively, the cerebral cortex has areas that enable learning, memory, and thought. It also helps form our individual personalities with complex behaviors that require integration of several cerebral and lower brain areas.

Deep within the white matter of the cerebral hemispheres are masses of gray matter called the basal nuclei (ganglia).
Their functions are concerned with certain subconscious aspects of voluntary movement: regulation of muscle tone, inhibiting tremor, and use of accessory movements such as arm swinging when walking.

**Cranial Nerves**

The 12 pairs of cranial nerves emerge from the brainstem with the exception of pair one, which originates from the temporal lobe and pair two from the occipital lobe. Some are purely sensory nerves, whereas others are mixed nerves. The impulses for sight, smell, hearing, taste, equilibrium, and somatic senses of supplied areas are all carried by cranial nerves to their respective sensory areas in the brain. Other cranial nerves carry motor impulses to muscles of the face, neck, shoulders, and tongue, or to glands. Cranial nerves III, VII, IX, and X contain axons of both the somatic and autonomic nervous systems. The functions of all the cranial nerves are summarized in Table 47.2.

**Autonomic Nervous System**

Autonomic nervous system (ANS) motor output provides dual innervation to effectors, that is, smooth muscle, cardiac muscle, and glands that produce the response (effect). These two divisions (sympathetic and parasympathetic) function in opposition to one another and their activity is integrated by the hypothalamus.

**LEARNING TIP**

The cranial nerves are easier to remember when a mnemonic device is used:

The cell bodies of the sympathetic pre ganglionic neurons are thoracolumbar (in the thoracic and lumbar segments of the spinal cord, Fig. 47.8). The sympathetic division is dominant in stressful situations such as fear, anger, anxiety, excitement, and exercise. The responses prepare the body for physical activity,
whether or not it is actually needed. Heart rate increases, vasodilation in skeletal muscles increases oxygen and glucose supply, bronchioles dilate to take in more air, and the liver converts glycogen to glucose to provide energy. The neurotransmitters of the sympathetic division are acetylcholine and norepinephrine. Acetylcholine is released by sympathetic preganglionic neurons; its inactivator is acetylcholinesterase. Norepinephrine is released by most sympathetic postganglionic neurons at the synapses with the effector cells; its inactivator is catechol-O-methyltransferase (COMT) or monoamine oxidase (MAO). Table 47.3 summarizes both ANS divisions.

Parasympathetic Division

The cell bodies of the parasympathetic pre ganglionic neurons are craniosacral (in the brainstem and the sacral segments of the spinal cord, Fig. 47.9). The parasympathetic division dominates during relaxed, nonstressful situations to promote normal functioning of several organ systems. Digestion proceeds normally, with increased secretions and peristalsis; defecation and urination may occur, and the heart beats at a normal resting rate (see Table 47.3). Acetylcholine is the neurotransmitter at all parasympathetic synapses, both preganglionic and postganglionic; it is inactivated by acetylcholinesterase.

### CRITICAL THINKING

Mrs. Stevens

- Mrs. Stevens receives albuterol treatments for her chronic obstructive pulmonary disease. The medication opens her airways effectively, but after her treatments, she often reports that her heart is racing. What part of the PNS do you think this medication affects?

Suggested answers are at the end of the chapter.

Aging and the Nervous System

With age, the brain loses neurons, but this is only a small percentage of the total and is not the usual cause of mental
Sympathetic preganglionic neurons begin within the spinal cord.

From the cell bodies, myelinated fibers reach to sympathetic ganglia, most of which exist in chains along both sides of the spinal cord (even though the illustration here depicts the ganglia only along one side). Because the ganglia lie close to the spinal cord, the preganglionic neurons are short.

Not all preganglionic neurons synapse in the first ganglion they encounter. Some travel up or down the chain to synapse with other ganglia at different levels. Others pass through the first ganglion to synapse with another ganglion a short distance away.

Unmyelinated postganglionic fibers leave the ganglia and extend to the target organs. Postganglionic fibers tend to be long.

FIGURE 47.8 Sympathetic nervous system. From Thompson, G. S. [2013]. Understanding anatomy and physiology. Philadelphia: F.A. Davis, p. 188.

impairment in older adults; far more common causes of mental changes include depression, malnutrition, infection, hypotension, and the side effects of medications. Some forgetfulness is to be expected, as is a decreased ability for problem solving (Fig. 47.10).

LEARNING TIP

Sympathetic—S is for STRESS RESPONSE: The sympathetic response is referred to as the fight-or-flight response. When thinking of the sympathetic nervous system, imagine getting away from a lion. You need dilated pupils to see the path better, copious production of sweat to lose heat through evaporation, increased rate and force of heart contraction to ensure that enough blood gets to the extremities so you can run faster, dilated bronchioles to get more oxygen to your muscles, decreased digestion

because that would be wasted energy, decreased urine output so you won’t have to stop for the restroom, and increased mental alertness so you are always aware of where the lion is.

Parasympathetic—P is for PEACEFUL: The parasympathetic nervous system brings the body back to balance and rest. It is sometimes referred to as the rest-and-digest response. Think, “There is no longer a lion. Now my body can go back to normal and start digesting and urinating again!”

NURSING ASSESSMENT OF THE NEUROLOGIC SYSTEM

The focus of a nursing neurologic assessment is to establish the present function of the patient’s neurologic system and to detect changes from previous assessments. A complete neurologic assessment, intended to determine the
existence of neurologic disease, is performed by a health care provider (HCP). A baseline neurologic assessment should be performed on every patient admission (Box 47-1). In addition to providing valuable information about the current functioning of the patient’s neurologic system, the assessment provides baseline data for later comparison. This is especially important if the patient has chronic neurologic deficits on admission.

Consider a patient admitted for surgery who has had a previous cerebrovascular accident resulting in paresis (weakness or partial paralysis) of the right arm. A complete neurologic assessment would document that the right arm is weaker than the left. If during the postoperative course you assess that both arms are equal in strength, you would want to notify the physician so the patient could be further assessed for possible causes of weakening of the left arm.

The results of the baseline assessment are valuable in planning and implementing safe care. For example, a patient who has a history of seizures needs a safe environment and careful monitoring, and all staff members who interact with such patients should be aware of how to respond to a seizure. Patients with dysphagia (difficulty swallowing) may need to have restrictions placed on the types of food or fluids they can have. This information must be consistently communicated to all staff involved in the patient’s care.

The frequency of neurologic assessments depends on the patient’s admitting diagnosis, the presence of any chronic neurologic disorders, and the current functioning of the patient’s neurologic system. Orders for neurologic assessments vary from every 15 minutes for an acutely ill or injured patient, to every 8 hours for a patient who is close to being discharged, to every 24 hours for a resident living in long-term care. It is always appropriate to assess a patient more often than ordered, based on observed changes in the patient’s condition, and to communicate the findings of those assessments to the HCP. Rapid detection and intervention may mean the difference between chronic dysfunction and recovery or even between life and death for the patient.

Parasympathetic fibers leave the brainstem by joining one of the following cranial nerves:

- **Oculomotor nerve (III):** Parasympathetic fibers carried in this nerve innervate the ciliary muscle, which thickens the lens of the eye, and the pupillary constrictor, which constricts the pupil.
- **Facial nerve (VII):** These parasympathetic fibers regulate the tear glands, salivary glands, and nasal glands.
- **Glossopharyngeal nerve (IX):** The parasympathetic fibers carried in this nerve trigger salivation.
- **Vagus nerve (X):** This nerve carries about 90% of all parasympathetic preganglionic fibers. It travels from the brain to organs in the thoracic cavity (including the heart, lung, and esophagus) and the abdominal cavity (such as the stomach, liver, kidneys, pancreas, and intestines).

Parasympathetic fibers leave the sacral region by way of pelvic nerves and travel to portions of the colon and bladder.

Unlike the ganglia of the sympathetic division, the ganglia of the parasympathetic division reside in or near the target organ. As a result, the preganglionic fibers of the parasympathetic division are long while the postganglionic fibers are short.

Because the ganglia are more widely dispersed, the parasympathetic division produces a more localized response than that of the sympathetic division.

**Health History**

To understand the patient’s neurologic status, ask about past and current symptoms, use of prescription and over-the-counter medications, use of recreational drugs, past surgeries, treatments, and risk factors such as family history, diet, exercise, sedentary lifestyle, caffeine intake, and recent stressors. Assessment of symptoms, as with other body systems, includes asking the **WHAT’S UP?** questions.

You should also obtain a history of the patient’s general health and then focus on any neurologic symptoms. Symptoms of neurologic disorders vary in type, location, and intensity. It is important to remember that some neurologic disorders can affect the patient’s ability to think, remember, speak, or interpret stimuli. It may be necessary to question significant others about duration and severity of symptoms. Some patients may not be able to recognize their own neurologic deficits. In such cases, the significant other usually initiates contact with the health care system and provides the medical and social history. See Table 47.4 for sample questions to ask if the patient has a change in mental status.

In addition to questioning the patient, the nurse observes the patient during the health history. Is he or she shifting positions and exhibiting signs of discomfort? Is the patient able to move about freely? Is he or she able to carry on a coherent conversation?

**Physical Examination**

The physical examination begins when you first meet the patient and evaluate the patient’s mental and physical status. The neurologic system is assessed using inspection, palpation, and percussion (with a reflex hammer). When conducting the mental status and cognitive portions of the examination, be aware that fatigue, illness, or medications can alter findings. When interpreting neurologic findings, be sure to consider the patient’s age, educational background, and cultural background.

**Level of Consciousness**

Level of consciousness exists along a continuum from full wakefulness, alertness, and cooperation to unresponsiveness to any form of external stimuli. A fully conscious patient responds to questions spontaneously. As consciousness becomes impaired, a patient may show irritability, a shortened attention span, or an inability to cooperate. The level of consciousness should be the first thing assessed.
The Aging Nervous System

- Increased syncope
- Decreased mental function
- Impairment in cognition, reasoning, judgment, and orientation
- Altered sleep patterns
- Decreased motor function
- More accidents and falls

**Box 47-1 Basic Neurologic Assessment**

Assess level of consciousness (patient’s response to verbal or tactile stimulation) and orientation.

Obtain vital signs (specifically blood pressure, pulse, and respirations).

Check pupillary response to light.

Assess strength and equality of hand grip and movement of extremities.

Determine ability to sense touch or pain in extremities.

During a neurologic examination because the information obtained can be used to modify the remainder of the examination if necessary. Keep in mind that a decrease in the level of consciousness can be caused by problems such as hypoxia, hypoglycemia, or intoxication, not just dysfunction of the neurologic system.

Many healthcare institutions use the Glasgow Coma Scale (GCS), which is an international scale used to assess level of consciousness (LOC) and document findings (Table 47.5). The GCS is used to evaluate patients who have a potential for rapid deterioration in consciousness. When assessing LOC, consider the patient’s physical ability to respond, taking into consideration trauma, medical condition, and medications. For example, a patient who cannot open his or her eyes because of facial trauma may still have an intact neurologic system.

Motor response is scored in the GCS based on following commands, responding to pain, or displaying abnormal postures. Abnormal postures include **decorticate** and **decerebrate**. In decorticate, or flexion, posturing, the patient’s arms are flexed at the elbow, the hands are raised toward the chest, and the legs are extended (Fig. 47.11A). This posture indicates significant impairment of cerebral functioning. In decerebrate, or extension, posturing, both the arms and legs are extended and the arms are internally rotated (Fig. 47.11B). This abnormal posturing indicates damage in the area of the brainstem.

The total possible score on the GCS ranges from 3 to 15. A score of less than 7 indicates a comatose patient and a score of 15 indicates the patient is fully alert and oriented. When used to score the effects of a head injury, a score of 13 or 14 indicates mild head injury, 9 to 12 indicates moderate injury, and any score of 8 or below indicates severe head injury. For all categories of the GCS, the type of painful stimuli required to elicit a response should be documented. Deterioration in the patient’s condition (i.e., a lowering of the GCS score) should be reported to the physician promptly.

**EVIDENCE-BASED PRACTICE**

**Clinical Question**

Is the Glasgow Coma Scale (GCS) the best tool for neurologic assessment?

According to a recent study by Sadaka, Patel, and Lakshmanan (2012), there has been a known problem with the GCS when used with intubated patients. A new scale has been developed, known as the Full Outline of Unresponsiveness scale (FOUR). Both scales were used to assess level of consciousness and predict the patient outcome after a traumatic brain injury. A high degree of consistency was found between the two scales. The conclusion was that the FOUR scale is an accurate predictor of outcome for TBI patients and had an advantage over the GCS when assessing an intubated patient. The FOUR evaluates four components: eye and motor responses, brainstem reflexes, and respiration.

** WORD BUILDING **

**decorticate**: de—down + corticate—cerebral cortex

**decerebrate**: de—down + cerebrate—cerebrum
### TABLE 47.4 COLLECTION OF DATA RELATING TO MENTAL STATUS

<table>
<thead>
<tr>
<th>Category</th>
<th>Questions to Ask During the Health History</th>
<th>Rationale/Significance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mental Status</td>
<td>What is your name? What is the month? Year? Where are you now?</td>
<td>Disorientation is often an initial sign of a neurologic disorder.</td>
</tr>
<tr>
<td>Intellectual Function</td>
<td>Subtract 7 from 100, then 7 from that answer, and so on (serial 7s).</td>
<td>Most people with intact neurologic function can complete serial 7s in about 90 seconds.</td>
</tr>
<tr>
<td>Thought Content</td>
<td>What would you do if you smelled smoke? Where would you put milk?</td>
<td>Assessment of the patient’s ability to interpret information and act appropriately is an important safety issue and activity of daily living.</td>
</tr>
<tr>
<td>Perception</td>
<td>Show patient pencil and pen and ask what each is.</td>
<td>Agnosia (inability to interpret or recognize familiar objects) can occur in stroke and brain lesions.</td>
</tr>
<tr>
<td>Language Ability</td>
<td>Read the following sentence: ____.</td>
<td>Different types of aphasia can result from injury to different parts of the brain.</td>
</tr>
<tr>
<td>Memory</td>
<td>Repeat these four or five words: ____. Repeat them again in 5 minutes.</td>
<td>Impaired memory can be affected by both delirium and dementia. Delirium can cause impaired immediate and short-term memory, whereas dementia not only affects immediate and short-term memory but also the ability to learn new information. It also may be related to stroke.</td>
</tr>
<tr>
<td>Pain</td>
<td>On a scale of 0 to 10 with 0 as no pain and 10 as the worst you have ever had, what is your pain level?</td>
<td>Pain perception may be altered or impaired by spinal injury, medications, alcohol, stress, and level of consciousness. Some spinal injuries may be critical, but the patient will not report pain.</td>
</tr>
</tbody>
</table>

The **Full Outline of UnResponsiveness (FOUR)** is a newer tool that has been introduced into many critical care and emergency department areas and has been shown to be as effective if not better than the GCS. A major benefit of using the FOUR is that no evaluation of verbal response is necessary, which is a problem when using the GCS with intubated patients. The FOUR uses four categories: eye response, motor movement, reflexes, and breathing pattern. A maximum of four points can be earned in each of the four areas. The terms **decorticate** and **decerebrate** are not used when assessing the motor response to prevent confusion. In addition, the brainstem is evaluated using both pupillary reflexes and corneal reflexes along with the cough reflex. Once each of the components is assessed and assigned a numerical value, the components are totaled. In general, the lower the FOUR Score is, the worse the patient is neurologically and the poorer the prognosis. Conversely, the higher the score, the better the prognosis (see Fig. 47.12).

*Note: This scale is for adults only. Criteria specific to children should be used for pediatric cases.

*To elicit pain, place pressure on a nailbed or on the trapezius muscle. Be sure to apply the stimulus long enough to elicit a response.

Mental status can be affected not only by the aging process but by a variety of neurologic disorders and injuries. A traumatic brain injury can result in memory impairment, delayed amnesia, affective (mood) disorders, and dementia. To assess...
Abnormal posturing.

(A) Decorticate posturing.
- Elbows flexed
- Arms adducted
- Feet plantar flexed
- Wrist and fingers flexed

(B) Decerebrate posturing.
- Forearms pronated
- Elbows extended
- Arms adducted
- Feet plantar flexed
- Wrist and fingers flexed

Eye response
- 4 = eyelids open or opened, tracking, or blinking to command
- 3 = eyelids open but not tracking
- 2 = eyelids closed but open to loud voice
- 1 = eyelids closed but open to pain
- 0 = eyelids remain closed with pain

Motor response
- 4 = thumbs-up, fist, or peace sign
- 3 = localizing to pain
- 2 = flexion response to pain
- 1 = extension response to pain
- 0 = no response to pain or generalized myoclonus status

Brainstem reflexes
- 4 = pupil and corneal reflexes present
- 3 = one pupil wide and fixed
- 2 = pupil or corneal reflexes absent
- 1 = pupil and corneal reflexes absent
- 0 = absent pupil, corneal, and cough reflexes

Respiration
- 4 = not intubated, regular breathing pattern
- 3 = not intubated, Cheyne-Stokes breathing pattern
- 2 = not intubated, irregular breathing
- 1 = breathes above ventilator rate
- 0 = breathes at ventilator rate or apnea
for cognitive impairment, the Mini-Mental State Examination (MMSE) or Confusion Assessment Method can be used. The Confusion Assessment Method uses the following criteria to help diagnose delirium (Waszynski, 2007):

- Acute onset and fluctuating course
- Inattention
- Disorganized thinking
- Altered level of consciousness

Find more about the Confusion Assessment Method at the Hartford Institute for Geriatric Nursing (http://consultgerim.org), an excellent collaborative website that provides bestpractice information related to older adults. A change in mental status should be taken seriously, especially when the patient takes multiple medicines or has had a recent change in medicines. A primary cause of delirium and acute states of confusion is adverse effects from medications.

When you assess cognitive function, you are evaluating the patient’s thinking capacity. You want to determine the length of attention span, ability to concentrate, judgment, memory, orientation, perception, problem-solving ability, and motor function.

You can learn a great deal about a patient’s mental capacities and emotional state by simply interacting with the patient. Behavior, mood, hygiene, grooming, and choice of dress reveal pertinent information about mental status. Mental status examinations can be performed to determine patients’ cognitive functioning, thought processes, and perceptions by observing the patient’s verbal and nonverbal responses to questions and specific requests. Table 47.4 includes some ways to assess these areas.

Orientation refers to the patient’s ability to comprehend himself or herself in relation to person, location (place), and time. A patient who is fully oriented is often referred to as “oriented times three.” Typical questions include, “What is your name? Where are you? What day is it?” (Keep in mind that we all forget the date from time to time!) You can also ask if the person knows what season it is (spring, fall, etc.). A resident of a long-term care facility who says he is “at home” may consider the facility his home and is not necessarily disoriented. Be sure your question is appropriate to the patient’s age, culture, living conditions, lifestyle, and medical condition. If the patient is unable to speak because of a stroke (expressive aphasia) or being intubated, do not rule out the possibility that the patient is oriented. Give expressively aphasic patients yes-or-no questions such as “Are you in a grocery store? Are you in a bowling alley? Are you in a hospital?” Patients may be able to answer with a shake of the head, eye blinks, or hand squeezes as instructed.

### Examination of the Eyes

Examination of the pupils is an important part of the neurologic assessment and cranial nerve evaluation. The size of the pupils at rest is documented in millimeters (Fig. 47.13). If the patient’s pupils are unusually large or small, determine whether the patient has had any medications that can affect pupil size. If the patient’s pupils are unequal in size (anisocoria), without a correlating diagnosis or symptoms, ask the patient or significant others if the patient normally has unequal pupils. Anisocoria may be congenital; it can also be caused by cataract surgery. Development of unequal pupils in a patient who previously had equal pupils is an emergency and should be reported to the physician immediately. Any deviation from the normal round shape of the pupils is documented.

Once the resting size of the pupils has been noted, the next step is to assess their response to light. In a darkened room, a light source (such as a flashlight) is directed at the pupil from the lateral aspect of the eye. This allows the examiner to see the direct and the consensual response to the light. A consensual response means that when one pupil is exposed to direct light, the other pupil also constricts. Absence of a consensual response may indicate a pathological condition in the area of the optic chiasm. Typically, the speed of the reaction to light is described as brisk, sluggish, or absent. Differences in the speed or size of constriction between the two pupils should be reported to the practitioner.

Accommodation is the process of visual focusing from far to near. To evaluate for accommodation, have the patient focus on an object at a distant point and then refocus on the object at a near point. Pupils should constrict with the adjustment to the near object and the eyes should converge. Upon completion of the assessment of the pupils, document your findings. PERRLA is a commonly used abbreviation to note that pupils are equal, round, and reactive to light and accommodation. Note, if you have not assessed for accommodation, then do not include the A in the acronym.

You will also evaluate for range of motion and for smoothness and coordination of movements. Eyes that move in the same direction in a coordinated manner are said to have a conjugate gaze. Conversely, a dysconjugate gaze is movement of the eyes in different directions. Some patients may be unable to move one or both eyes in a specific direction; this is called ophthalmoplegia. It is often documented as “limited extraocular movements.” Always document what the limitation is (e.g., “Patient is unable to look laterally with left eye”). This allows colleagues to compare their findings with yours and detect any changes.

**Nystagmus** is involuntary movement of the eyes. Nystagmus varies in the speed of the movement and the direction. Horizontal nystagmus is the most common. Common causes

- **WORD BUILDING**
  - **aphasia**: absence + phasia—speech
  - **anisocoria**: aniso—unequal + coria—pupil
of nystagmus are phenytoin (Dilantin) toxicity and injury to the brainstem.

**Examination of Muscle Function**

Examine muscle groups systematically in the upper extremities and then the lower extremities, comparing right to left. Compare muscle groups for symmetry of size and strength. Keep in mind the patient’s age and general physical condition when evaluating muscle strength. You would not expect the same amount of strength from a 75-year-old woman as from a 20-year-old man. If the patient has chronic neurologic deficits, ask if the results of the assessment are different from his or her usual level of function.

Many HCPs use a 5-point scale to document muscle strength. A score of 5 describes a patient who is able to move the extremity against gravity and the resistance of the examiner, displaying normal muscle strength. If the examiner is able to provide more resistance than the patient can overcome with active movement, the score is 4. If the patient can move the extremity only against gravity, the score is 3. If gravity must be eliminated by having the examiner support the extremity to allow the patient to move the extremity, the score is 2. A score of 1 is given if there is no active movement of the extremity, but a minimum muscular contraction can be palpated. If the examiner is unable to detect any muscular function, a score of 0 is given.

To test the deltoid muscles, ask the patient to raise his or her arms at the shoulder. Have the patient resist as you push down on the upper arms. The biceps are tested by having the patient flex the arm at the elbow and bring the palm toward the face, then resist as you attempt to straighten the arm by pulling on the forearm. With the arm similarly flexed, ask the patient to straighten the arm while you resist the movement.

Hand grasps are tested by having the patient squeeze your fingers. Remember to cross your index and middle fingers to prevent the patient from hurting your fingers. If the patient does not release the grasp when told to, it is a reflex grasp, not a response to command. A reflex palmar grasp may indicate a pathological condition of the frontal lobe.

Assess for arm drift by asking the patient to hold both arms straight in front with the palms up and while keeping the eyes closed. A downward drift of the arm or rotation so that the palm is down indicates impairment of the opposite side of the brain. If a pathological condition is present, arm drift may be apparent before differences in muscle strength can be detected.

Assessment of leg muscle strength begins with the iliopsoas muscle. Place your hand on the patient’s thigh and ask the patient to raise the leg, flexing at the hip. Hip abductors are tested by having the patient bring his or her legs together against your hands. The hip abductors and gluteus medius and minimus are tested by having the patient move the legs apart against resistance. Hip extension by the gluteus maximus is tested by placing the hand under the thigh and having the patient push down with the leg. The quadriceps femoris extends the knee and is tested by having the patient attempt to straighten the leg at the knee. The hamstrings are responsible for knee flexion and are evaluated by having the patient attempt to keep the heel of the foot against the bed or chair rung. Dorsiflexion is tested by having the patient pull the toes toward the head against resistance. Plantar flexion is tested by having the patient push against the examiner’s hand with the ball of the foot.

**Babinski’s reflex** is tested by firmly stroking the sole of the foot. Normal response is flexion of the great toe. If the great toe extends and the other toes fan out, neurologic dysfunction should be suspected if the patient is more than 6 months old. Deep tendon reflexes are not usually part of a routine nursing assessment. The patient’s gait should be assessed to detect any neurologic dysfunction and also to assess ability to ambulate safely. Patients who stagger, weave, or bump into objects may need assistance with walking.

**Romberg’s test** is performed by having the patient stand with feet together and eyes closed. Be sure to stand close to the patient, especially if he or she is an older adult, to prevent falling. A negative Romberg’s test means that the patient experiences minimal swaying for up to 20 seconds. A patient who experiences swaying or who leans to one side is said to have a positive Romberg’s test. A positive Romberg’s test may be seen in cerebellar dysfunction.

---

**BE SAFE!**

A positive Romberg’s test in an older adult is expected as a result of normal aging changes in the cerebellum. Be sure to protect the patient with a positive result from falls. A gait belt may be helpful when assisting the patient with ambulation.

---

**Examination of Cranial Nerves**

The cranial nerves are usually not examined in depth during a routine bedside neurologic assessment. Testing requires a patient who is able to cooperate with the examiner. Table 47.6 provides basic testing techniques that offer a basic assessment of cranial nerve function.

**Summary of Examination Findings**

In all cases, the findings of the neurologic examination should be correlated with the remainder of the physical examination findings. A decreased level of consciousness, coupled with a decreased oxygen saturation on pulse oximetry, point to hypoxia as a cause. Correlation of vital signs with neurologic signs is particularly important. Bradycardia, increasing systolic blood pressure with widening pulse pressure, and irregular respirations, commonly referred to as Cushing’s triad, are late indications of increasing intracranial pressure. These findings, in conjunction with a unilateral dilated pupil, may indicate impending herniation of the brain (discussed further in Chapter 48).
Laboratory Tests

Specific diagnostic blood tests do not exist for neurologic disorders. However, depending on the history and physical examination, the HCP may include laboratory tests to look for underlying causes of symptoms: thyroid hormone levels, vitamin B₁₂, complete blood count (CBC), electrolytes, creatine kinase and isoenzymes (CK), venereal disease research lab (VDRL) test (for syphilis), liver function, and renal function. Measurement of erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count may indicate an infection, such as meningitis. Hormone levels, such as prolactin or cortisol, may indicate dysfunction of the pituitary gland related to a brain tumor. Anticholinesterase testing and antibody titers are useful in diagnosing myasthenia gravis. Research is ongoing to develop a blood test for Alzheimer's disease.

Lumbar Puncture

Cerebrospinal fluid (CSF) may be obtained via lumbar puncture and evaluated for glucose and protein levels, the presence of bacteria and WBCs, levels of immunoglobulin, antibodies, and culture and sensitivity. See Appendix A for nursing care of a patient undergoing lumbar puncture.

CRITICAL THINKING

Tim Thompson

You are caring for Tim, a 78-year-old man admitted with heart problems. As you enter his room with his afternoon medications, you find Tim confused. He thinks he is at home, that the year is 1968, and he does not understand who you are or why you are there. He recognizes his wife, who is at his bedside, and he knows his own name.

1. How would you describe and document his mental status?
2. What additional data do you need to decide how to proceed?
3. What may have contributed to his confusion?
4. What members of the health team can you collaborate with in caring for Tim?

Suggested answers are at the end of the chapter.

NURSING CARE TIP

The idea of a needle being introduced into the spinal canal is frightening to many people. Give simple, clear directions to the patient; help the patient maintain his or her position; and provide emotional support throughout the procedure.

X-Ray Examination

Spinal x-ray examinations are done to determine the status of individual vertebrae and their relationship to one another. If the patient experiences pain with certain movements, he or
Chapter 47  Neurologic System Function, Assessment, and Therapeutic Measures

she may be asked to flex and extend the area of the spine being examined while the radiographs are taken. This allows detection of abnormal movement of the vertebrae. If the patient may have sustained trauma to the spine, particularly the cervical spine, radiographs are taken before the immobilizing devices are removed. Skull radiographs may be taken to detect skull fractures or foreign bodies. No special nursing care is required.

**Computed Tomography**

A computed tomography (CT) scan is used for diagnosing neurologic disorders of the brain or spine. Some of the disorders that can be detected by CT are hemorrhage, altered ventricle size, cerebral atrophy, tumors, skull fractures, and abscesses. CT is used when magnetic resonance imaging (MRI) is contraindicated because of metal aneurysm clips or other metal implants.

The scan may be performed with or without radiopaque contrast material to enhance the clarity of the images. Contrast material is most commonly used if a tumor is suspected or following surgery in the area to be scanned. CT scans are commonly used in emergency evaluations because they can be done quickly, an important consideration if the patient is ventilated or unstable.

**Nursing Care**

During the CT scan, the patient must lie still on a movable table. Noncontrast scans take about 10 minutes; contrast scans take 20 to 30 minutes. Patients who are receiving dye should be warned that they may feel a sensation of warmth following the injection; warmth in the groin area might make them feel as though they have been incontinent of urine. Nausea, diaphoresis, itching, or difficulty breathing can indicate allergy to the dye and should be reported immediately to the physician or nurse practitioner. Sedation may be required for patients who are agitated or disoriented. Patients who are in pain may need pain medication before the examination. See Appendix A for nursing care of a patient undergoing a CT scan.

**Magnetic Resonance Imaging**

MRI is used for diagnosis of degenerative diseases such as multiple sclerosis, arteriovenous malformations, small tumors, hemorrhages, and cerebral and spinal cord edema. An MRI of the mediastinal cavity will determine if the thymus gland is enlarged and facilitate diagnosis of myasthenia gravis. It is a longer procedure and may be difficult for unstable, disoriented, or ventilated patients. As with a CT scan, the MRI can be done with or without contrast material. Some facilities have the capability to perform magnetic resonance angiograms (MRAs). This test allows visualization of blood vessels and assessment of blood flow without being as invasive as a traditional angiogram. See Appendix A for nursing care of a patient undergoing MRI.

**Angiogram**

An angiogram provides information about the structure of specific vessels, as well as overall circulation to an area. See Appendix A for nursing care of a patient undergoing an angiogram.

**Myelogram**

A myelogram is an x-ray examination of the spinal canal and its contents after injection of contrast material. Compression of nerve roots, herniation of intravertebral disks, and blockage of cerebrospinal fluid circulation can all be detected by myelogram. See Appendix A for nursing care of a patient undergoing a myelogram.

**Electroencephalogram**

Electrical activity of the brain is evaluated by use of an electroencephalogram (EEG). Analysis of the tracing can identify areas of abnormality, such as a seizure focus or areas of slowed activity.

**Moving and Positioning**

Patients who have pain may need help changing positions and ambulating. Use of heat, cold, or analgesics may allow the patient to be more independent in mobility.

If the patient has sensory loss, make sure that no part of the body is inadvertently compressed (e.g., a hand caught under a hip or the scrotum compressed between the legs). Pressure ulcers are a primary concern with the patient who is unable to move independently. Collaborate with the physical therapist to determine positioning techniques that maximize the chance of useful recovery.

Patients with paresis, paralysis, or paresthesia (abnormal sensation such as burning or tingling) may be partially or completely dependent in moving and positioning. Take care to maintain the body in functional positions when routine position changes are made. This means keeping the trunk, extremities, hands, and feet in usable positions—for example, hands can be splinted to keep the thumb and fingers opposed, or tennis shoes can be used to keep the feet in an appropriate position for standing or walking.

**Contractures** and footdrop are complications that are often associated with neurologic disorders. Contractures are permanent muscle contractions with fibrosis of connective tissue that occur from lack of use of a muscle or muscle group. They cause permanent deformities and prevent normal functioning of the affected part. Footdrop occurs when the feet are not supported in a functional position and become contracted in a position of plantar flexion (Fig. 47.14). Use
footboards, high-top tennis shoes, and splints to help prevent footdrop. Splints are commonly used to prevent contractures of the upper and lower extremities and to keep the affected parts in a functional position. If splints are used, the patient must be evaluated for and protected from discomfort and skin breakdown at the splint site.

Mobilization should begin as soon as a patient is medically stable. Initially this may involve the use of a cardiac chair if the patient is unable to bear weight. Transfer of the patient to a bedside chair or use of ambulation aids may require a multidisciplinary approach. Be careful to recognize any physical or cognitive deficits that might affect safety and adjust the environment to protect the patient. This includes communicating any safety concerns to unlicensed personnel who interact with the patient.

Activities of Daily Living
The effects of neurologic disorders on activities of daily living (ADLs) can range from an inconvenience to complete dependence. Patients may have trouble bending over to put on their shoes and socks, lifting a full cooking pot, or caring for an infant. A quadriplegic patient may be completely unable to perform ADLs but can be taught to direct his or her own personal care. Encourage patients to use strategies they learned in occupational or physical therapy.

Assessment of a hospitalized patient should include a discussion of the strategies the patient normally uses at home to accomplish ADLs. Every attempt should be made to continue to use these strategies. This is particularly true if the patient is admitted to a long-term care facility. Patients who have intact cognitive function should be included in care planning and encouraged to work collaboratively with caregivers. If the strategies the patient uses during ADLs must be changed (e.g., if the patient’s transfer technique is unsafe), be sure to explain the rationale for the changes to the patient and significant others. If patients have impaired cognitive function, try to maintain a specific routine that is as close to their normal environment as possible. Normalizing routines may help patients adapt to a change in environment and maximize their ability to function.

Communication
The communication problems associated with neurologic disorders have a variety of etiologies. Some neurologic disorders cause difficulty speaking (dysarthria). Dysfunction of the lips, tongue, or jaw makes speech difficult or impossible to understand. When dysarthric individuals know what they want to say but cannot be understood, they can become very frustrated. This frustration is compounded if the patients are treated as if they have cognitive deficits merely because they have difficulty communicating.

Patients who have had a stroke can experience different types of aphasia. Expressive aphasia is difficulty or inability to verbally communicate with others. The patient may be able to speak in sentences but inappropriately substitute words, such as “The sky is dish.” Word-finding difficulty is another type of expressive aphasia. These patients may tell you “I want a . . .” and then be unable to complete the sentence. In severe cases of aphasia, the patient may make sounds that resemble words or may only utter sounds. For individuals with no intelligible speech or with word-finding difficulty, a picture board with commonly used items may facilitate communication. (See an example of a picture board in Chapter 49.) Keep in mind that patients with expressive aphasia may answer yes to all questions rather than just those for which yes is correct. The same is true of answering no. This is one reason why a nurse should never ask a patient, “Are you Mrs. Gonzalez?” An aphasic patient may say yes even if that is not her name. Instead, ask the patient to state her name. Always check the identification band.

For patients who substitute words, simply correct the substitution and continue the conversation. Patients with expressive aphasia are often very aware of and frustrated by their difficulty communicating. Give them time to try to express themselves. If you cannot understand them, offer possibilities based on the situation. If the patient is sitting in the chair, ask if he or she wants to go back to bed or wants to use the bathroom. If the patient is restless, ask if he or she is in pain.

Some patients use the same word in response to all questions, and for a few patients, that word is a profanity. This is very difficult for significant others to deal with, particularly if swearing is not something the patient normally did. Make it clear to the family that you understand that this behavior is part of the patient’s illness.

Receptive aphasia affects the patient’s ability to understand spoken language. Again, the severity of the aphasia varies.
Some patients may understand simple directions such as “sit down” or “squeeze my fingers.” In other cases, the nurse may need to pantomime the action the nurse wants the patient to perform, such as showing the patient pills and then mimicking taking the pills and drinking water.

**BE SAFE!**

If the patient has receptive aphasia, assume that he or she cannot understand or follow safety instructions, such as “Do not stand up until I get back.” Even going around the corner to get water can give a patient enough time to try to stand up and subsequently fall.

**Nutrition**

Alterations in the ability to maintain an adequate nutritional intake can have many causes. The level of consciousness may be depressed enough that the patient does not recognize that she or he is hungry or thirsty. Decreased level of consciousness or cranial nerve dysfunction may impair the patient’s ability to swallow safely. Severe weakness may limit the patient’s ability to take in enough food to meet the body’s requirements. These conditions are often compounded by the increased metabolic rate that accompanies neurologic injury or illness.

If there is any question of the patient’s ability to swallow, a swallowing evaluation should be performed by a speech therapist. Some institutions use a radiological examination to evaluate the ability to swallow. A small amount of barium is added to food or fluid, and fluoroscopy is used while the patient swallows. This allows visualization of the path of the food or fluid. Patients with swallowing difficulty (dysphagia) may have better success with foods or thick liquids rather than thin fluids. Liquids may be thickened with special thickening agents to allow easier swallowing. All patients should be positioned as upright as possible while eating or drinking, and patients who have difficulty swallowing should be monitored during eating and not left alone.

If weakness or fatigue is the cause of decreased nutritional intake, several modifications are possible. Serving small portions of food more frequently can increase intake. Using high-protein, high-calorie foods and supplements increases the nutritional content of small amounts of foods.

For patients who cannot swallow or who cannot swallow enough food, enteral tube feedings may be needed. If enteral feedings are anticipated to be for a short duration, a nasogastric tube may be used. The disadvantages of nasogastric tubes include impairment of the integrity of nasal skin and the risk of aspiration. The risk of aspiration in neurologically impaired patients who have cognitive impairments is increased because these patients may pull out the nasogastric tube due to their lack of understanding the purpose of the tube. If long-term enteral feedings are anticipated, a gastrostomy tube may be placed directly through the abdominal wall into the stomach. This feeding method has the advantage of reducing the risks of aspiration and eliminating nasal skin breakdown.

**Family**

When working with patients who have a neurologic deficit, whether acute or chronic, in the hospital, extended care facility, or at home, the family should be included in their care and rehabilitation. Depending on the patient’s diagnosis and prognosis, the family will need support from staff. It is rewarding to see the patient who has had an accident recover with rehabilitation, but it is also rewarding to promote quality of life for the patient with Alzheimer’s disease and his or her family. Communication with the family regarding patient improvements and information about the illness is extremely important. Include the family in the patient’s care, such as bathing, feeding, and grooming. Suggest that the family participate in physical, occupational, and speech therapy sessions. Education is of vital importance, especially if the patient is going to be discharged home. Direct the patient and family to support groups and case managers for information regarding financial assistance and community resources during rehabilitation.
CRITICAL THINKING

■ Mrs. Stevens

Albuterol is an adrenergic agonist (sometimes called a sympathomimetic), which is given to stimulate the sympathetic nervous system, resulting in open airways in patients with respiratory disease. However, it can also stimulate the cardiac system and cause a rapid heart rate and increased blood pressure. Be sure to monitor vital signs in patients receiving medications that affect the autonomic nervous system.

■ Tim Thompson

1. He is alert but confused, oriented to person only.
2. The nurse should ask his wife if this has ever happened before, check his medical history for any disorders that may contribute to neurologic dysfunction, do a quick neurologic examination to determine if any additional deficits exist, check vital signs and pulse oximetry if available, and notify the physician immediately if the symptoms are a new finding.
3. Some possible explanations to explore include hypoxemia, stroke, worsening heart problems causing inadequate flow of blood to the brain, hypoglycemia, or even confusion (delirium) related to a sudden transition from home to an unfamiliar environment.
4. Consider based on further assessment (as noted in #2 and 3) if there may be a need to contact the HCP for evaluation. Involve a respiratory therapist, electrocardiogram technician, or others based on assessed needs.

REVIEW QUESTIONS

1. What assessments are included in the FOUR Score coma scale? Select all that apply.
   1. Eye response
   2. Motor response
   3. Brainstem reflexes
   4. Respiration
   5. Verbal response

2. Which instruction would the nurse provide for the patient when testing the trigeminal nerve?
   1. “Stick out your tongue.”
   2. “Turn your head side to side.”
   3. “I am going to shine a light into your eyes and observe your pupils.”
   4. “Close your eyes and tell me where you feel the cotton touching your face.”

3. Which of the following is a symptom of increasing intracranial pressure that should be reported immediately to the primary care provider?
   1. Constricted pupils
   2. Decreasing level of consciousness
   3. Narrowing pulse pressure
   4. Bradypnea

4. What are the normal effects of aging on the CNS? Select all that apply.
   1. Increased postural stability
   2. Reduced blood flow to the brain
   3. Impaired short-term memory
   4. Sleep disturbances
   5. Loss of deep tendon reflexes
   6. Decrease in acetylcholine

5. The nurse knows the patient understands teaching about an angiogram when the patient makes which of the following statements?
   1. “A small needle will be inserted into my spinal column to withdraw fluid for examination.”
   2. “I will be in a large machine that uses magnetic energy to create images; it has a noisy knocking sound.”
   3. “Electrodes will be placed on my head to monitor electrical activity in my brain.”
   4. “A catheter will be placed in an artery in my groin, and dye will be injected that will make my vessels show up on x-ray.”
6. A patient has returned from having a CT scan with contrast. Which of the following should be a priority in the hours after the scan?
   1. Ambulation
   2. Drinking fluids
   3. Turning side to side
   4. Coughing and deep breathing
